The structural changes of a (111) oriented CeO₂ film grown on a hex-Pr₂O₃(0001)/Si(111) system due to post deposition annealing are investigated. X-ray photoelectron spectroscopy measurements revealing the near surface stoichiometry show that the film reduces continuously upon extended heat treatment. The film is not homogeneously reduced since several coexisting crystalline ceria phases are stabilized due to subsequent annealing at different temperatures as revealed by high resolution low energy electron diffraction and x-ray diffraction. The electron diffraction measurements show that after annealing at 660°C the t-phase (CeO₁₂) is formed at the surface which exhibits a (\(\sqrt{7} \times \sqrt{7}\))R19.1° structure. Furthermore, a (\(\sqrt{27} \times \sqrt{27}\))R30° surface structure with a stoichiometry close to Ce₂O₃ is stabilized after annealing at 860°C which can not be attributed to any bulk phase of ceria stable at room temperature. In addition, it is shown that the fully reduced ceria (Ce₂O₃) film exhibits a bixbyite structure. Polycrystalline silicate (CeSi₅O₁₄) and crystalline silicide (CeSi₁.₆₇) are formed at 850°C and detected at the surface after annealing above 900°C.

1 Introduction

Ceria plays a key role in the field of catalysis. For instance, ceria is used in several reactions like the three-way automotive exhaust catalysis or the generation of hydrogen. The catalytic activity is strongly influenced by oxygen vacancies especially at the surface. Hence, it is necessary to control the density and distribution of oxygen vacancies to build ceria based catalysts with tailored reactivity and selectivity. For obtaining a deep insight into the complex chemical reactions a single crystalline film with (111) orientation can be used as a ceria model catalyst where the atomic structure of surface and sub-surface oxygen vacancies is well known. Using a two-dimensional film instead of a polycrystalline three dimensional structure facilitates the use of variety of surface science techniques since these films exhibit a well-defined crystalline structures and surface morphology.

Here, silicon with (111) orientation is a well-suited substrate since ceria exhibits a small lattice mismatch (-0.35%) with respect to Si(111). Furthermore, ultrathin ceria films on Si substrates are very attractive since ceria is well-known as insulating layer for functional oxide integration in the field of micro- and nanoelectronics due to its high electrical constant (≈ 26). In addition, recent studies reveal the existence of room temperature ferromagnetism (RTFM) in doped and reduced ceria giving the opportunity of combining future spintronic devices with the existing silicon based technology. Oxygen vacancies have a strong influence on the magnetic properties in reduced ceria. However, the origin of this magnetism has not unambiguously been resolved up to now. The controlled generation of oxygen vacancies with long range order, as presented in this study, can be used to examine the role of oxygen vacancies in future studies elucidating the magnetic properties in more detail.

For bulk materials, the cerium-oxygen phase diagram exhibits several intermediate phases between the highest (CeO₂) and lowest oxidation state (Ce₂O₃). It is still a challenge to stabilize intermediate phases for thin films with high structural control. Recently, we have demonstrated that it is possible to stabilize the surface of the ceria t-phase (CeO₁₂) on a hex-Pr₂O₃(0001)/Si(111) system due to the reduction of Ce₂O₃ film. However, it is not yet clear whether the entire film is reduced to the Ce₂O₃ structure and whether it is possible to stabilize other intermediate phases. Therefore, we conduct a detailed study of the structural changes of a 250 nm CeO₂(111) film grown on a hex-Pr₂O₃(0001)/Si(111) system addressing, both, the surface and the bulk stoichiometry and crystal structure for different post deposition annealing (PDA) temperatures. The oxidation state of the surface is determined via x-ray photoelectron spectroscopy (XPS) while experiments with high resolution low energy electron diffraction combined with spot profile analysis (SPA-LEED) are performed to determine the changes in the atomic structure at...
the surface. In addition, transitions of the crystal structure throughout the film are investigated with synchrotron based in-situ x-ray diffraction (XRD) measurements.

2 Experiment

![Diagram](Schematic drawing of the investigated system. XPS and LEED are used to probe the near surface region while changes of the entire structure are studied by XRD.)

Ceria films are grown via molecular beam epitaxy (MBE) on boron doped 4° Si(111) wafers (σ = 5 - 15 Ωcm) which are cleaned and hydrogen terminated according to the recipe described in Ref. 23. After loading the wafer into an ultrahigh vacuum (UHV) chamber (base pressure 10^{-10} mbar) and annealing at 700 °C for 5 min, the Si(111)(7 × 7) surface reconstruction is obtained. An ultrathin hex-PrOx(0001) buffer layer is grown at a substrate temperature of 625 °C and a deposition rate of 3 nm/min. 24 The growth is monitored via reflection high-energy electron diffraction (RHEED) and the deposition is stopped after complete coverage of the substrate is reached (thickness ≈ 3 nm). Afterwards, a cub-CeO$_2$(111) film (thickness ≈ 250 nm) is deposited using the same substrate temperature and deposition rate. The CeO$_2$(111) film exhibits the fluorite crystal structure and a high crystalline quality as confirmed by ex-situ XRD (data not shown).

The surface characterization is performed in two different UHV chambers (base pressure 10^{-10} mbar both). The first chamber is equipped with a SPA-LEED system and the sample are annealed via resistive heating of the Si substrate. XPS measurements with Al K$_\alpha$ radiation (1486.6 eV) are performed in a second chamber where the surface structure is controlled with conventional LEED while the samples are annealed via filament heating. For both experimental setups, samples are successively annealed for 30 min and the temperature is controlled with an infrared (IR) pyrometer. After each PDA step the samples are cooled to room temperature (RT) to perform the measurements. When resistive heating is used, samples cool to room temperature almost immediately (cooling rate ≈ 500°C/min). If annealed via filament the sample cooling takes several hours (cooling rate ≈ 5°C/min) due to the large heat capacity of the sample holder.

The exposure of praseodymia films to an oxygen plasma has proven to be a superior method to gain high quality praseodymium dioxide (PrO$_2$) surfaces 25 and here we transfer this concept to ceria films. Hence, prior to the SPA-LEED and XPS experiments, samples are transferred to an in-situ plasma chamber (base pressure 10^{-7} mbar) and exposed to an oxygen microwave plasma (2.45 GHz) for 15 min to clean the surface and to reduce the number of oxygen vacancies at the surface. The plasma parameters are 80 sccm gas flow, 0.26 mbar oxygen pressure and 360 W power. Due to this treatment, the overall intensity of the XP spectra increases and the previously present small carbon 1s signal (E$_B$ = 284 eV) due to carbon contaminations vanishes (data not shown). Furthermore, in the electron diffraction measurements the diffuse background intensity is drastically reduced and strong charging effects appear indicating the high quality of the film. Hence, oxygen plasma treatment is a suitable method for cleaning and improving the crystalline quality of CeO$_2$ films.

For the structural characterization of the entire film, untreated samples are investigated with in-situ x-ray diffraction (XRD) measurements carried out in a modified version of the high vacuum (HV) reaction chamber (base pressure 10^{-8} mbar) presented in Ref. 25. The heating stage has been modified to enable resistive heating and an IR pyrometer was added for temperature control. The HV reaction chamber was mounted on a six-circle diffractometer at beamline W1 at DESY (Hamburg, Germany) facilitating diffraction studies with a photon energy of 10.5 keV. All measurements are performed at RT.

A schematic drawing of the investigated system is shown in Fig. 1.

3 Results

3.1 XPS

We determine the stoichiometry of the ceria surface after successive annealing cycles at different temperatures via XPS. The different oxidation states of ceria have extensively been studied by XPS in the past 27-30. Factor analysis studies have shown that the reduction process of ceria can be described by the two components of Ce$^{3+}$ and Ce$^{4+}$. Therefore, the oxidation state of the surface can be determined with high accuracy using a superposition of Ce 3d spectra of both Ce$_2$O$_3$ and CeO$_2$ since these spectra solely containing Ce$^{3+}$ and Ce$^{4+}$, respectively. The plasma treated sample is used as the CeO$_2$ reference spectrum while the Ce$_2$O$_3$ reference spectrum is obtained after annealing the sample at 890 °C with respective results shown in Fig. 2.
to expected bixbyte cub-Ce$_2$O$_3$ phase (cf. Fig. 6) while silicide is formed at higher temperatures as further discussed in the following. Furthermore, these reference spectra are in very good agreement with previously calculated spectra by Kotani et al.\textsuperscript{35}

Fig. 2 shows a series of Ce 3d XP spectra with the corresponding fits after successive annealing cycles at different temperatures. Prior to the fitting, a Shirley background is subtracted and the area underneath the peaks is normalized to unity. The fits are in very good agreement with the measured spectra allowing a determination of the Ce$^{3+}$/Ce$^{4+}$ ratio with an accuracy of 3%. The spin-orbit splitting in all Ce 3d spectra attributed to ceria is $\approx 18$ eV.

In the following, the origin and nomenclature of the peaks appearing in the 3d spectra presented in Fig. 2 is briefly introduced according to Kotani’s theory. Valence band holes and core holes are denoted with $v$ and $c$, respectively. The ground state of CeO$_2$ consists of the hybridization of the 4f$^0$ and 4f$^1$ configuration according to Kotani’s theory which leads to three final states ($x$, $y$, $z$) in each of the 3d$_{5/2}$ and 3d$_{3/2}$ components. The peaks labeled with $x$ and $y$ correspond to the bonding and antibonding final states of the strongly hybridized 4f$^1$ and 4f$^2$ configurations while the peak labeled with $z$ corresponds to the pure 4f$^2$ final state. On the contrary, the ground state of Ce$_2$O$_3$ exhibits only the pure 4f$^4$ configuration, which leads to two final states in each 3d$_{5/2}$ and 3d$_{3/2}$ component. The peaks labeled with $u$ and $v$ in the Ce 3d spectrum of Ce$_2$O$_3$ correspond to the bonding and the antibonding final states of the hybridized 4f$^3$ and 4f$^4$ configurations, respectively.

Fig. 3 presents the amount of Ce$^{3+}$ cations at the surface near region (inelastic mean free path $\lambda \approx 10$ Å in CeO$_2$)\textsuperscript{34} of the film after the different annealing steps. The surface reduces continuously as shown by the increasing amount of Ce$^{3+}$ cations with increasing PDA temperature. Until a PDA temperature of $\approx 800^\circ$C is reached, the Ce$^{3+}$ concentration shows only a slight increase. Thereafter, the oxygen release at the surface is drastically increased. After PDA treatments with temperatures higher than 890° the peaks labeled with $u$ and $v$ shift $\approx 1.2$ eV and $\approx 2.8$ eV to lower binding energies, respectively. In addition, the intensity of the peak labeled with $v$ is strongly reduced. This 3d spectrum appears like a metallic cerium spectrum\textsuperscript{36,37} superimposed with a weak Ce$_2$O$_3$ spectrum\textsuperscript{35}.

These results are supported by Ce 4d spectra presented in Fig. 4 that show the transition from a CeO$_2$ to a Ce$_2$O$_3$ spectrum with increasing PDA temperature. The measurements of the untreated and at 890°C annealed sample are in good agreement with the spectra of 4d CeO$_2$ and Ce$_2$O$_3$ calculated by Kotani et al.\textsuperscript{35}, respectively. The 4d spectra are only slightly separated in a 4d$_{5/2}$ and 4d$_{3/2}$ component since the spin orbit splitting is much weaker than for the 3d spectra. Furthermore,
this weak splitting cannot be resolved due to the strong overlapping multiplet coupling of the 4d and 4f states. Similar to the Ce 3d spectra, the intermediate spectra consist of a superposition of the CeO$_2$ and Ce$_2$O$_3$ spectra. The spectral weight of the characteristic features attributed to the CeO$_2$ 4d spectrum, e.g. the components located at $E_B = 125.5$ eV and $E_B = 122.2$ eV, decreases with increasing PDA temperature while the spectral weight of the characteristic features attributed to the Ce$_3$O$_2$ 4d spectrum increases. Furthermore, a strong Si 2p signal ($E_B = 100.3$ eV) close to the Ce 4d signals appears after annealing at 1050$^\circ$C indicating film decomposition by the diffusion of silicon to the surface.

Fig. 5 shows the O 1s spectra after subsequent annealing at different temperatures. For each measurement the spectrum is normalized to the area of the Ce 3d peaks. The O 1s peak attributed to ceria is located at $E_B = 530.2$ eV and exhibits a very weak shoulder at $E_B \approx 532$ eV. The origin of this shoulder is not clear. Some authors assign this shoulder to isolated oxygen vacancies in the ceria lattice$^{27}$ while others attribute it to surface impurities like hydroxyl groups.$^{28,38,39}$

The intensity of the O 1s signal attributed to ceria decreases with higher PDA temperatures which is consistent with the increase of the Ce$^{3+}$ signal in the Ce 3d spectra due to oxygen loss during film reduction. However, the weak shoulder is almost unchanged during the PDA treatment. Taking into account our LEED results, which prove that ordered oxygen vacancies emerge at the surface (cf. Sec. 3.2), we conclude that surface contamination is the origin of the shoulder and not oxygen vacancies. On the contrary, the full width at half-maximum (FWHM) of the O 1s peak increases from $\approx 1.6$ eV to $\approx 2.5$ eV after annealing above 800$^\circ$C. A possible explanation for this effect is a roughening of the surface due to oxygen vacancies caused by the massive release of oxygen in this temperature region (cf. Fig. 3). After annealing above 900$^\circ$C the intensity of the O 1s peak attributed to ceria is drastically decreased which is in good agreement with the Ce 3d spectra and point to the formation of silicide or silicate instead of oxide. Thus, large areas of the surface are transformed to silicide or silicate and that only a small amount of ceria is left at the surface.

![Fig. 3 Plot of the Ce$^{3+}$ concentration as determined by the analysis of the Ce 3d spectra against the annealing temperature. The near surface region is continuously reduced with increasing temperature. After annealing at temperatures above 800$^\circ$C, the Ce$^{3+}$ concentration increases drastically.](image)

![Fig. 4 XP spectra of the Ce 4d region normalized to the Ce 3d signal. After annealing at 1050$^\circ$C a strong Si 2p peak ($E_B = 100.3$ eV) appears.](image)
indicating the formation of tetrahedral pyramids on the ceria.

Structural changes at the surface are investigated with electron diffraction measurements. Fig. 6 shows diffraction patterns of the appearing structures. A hexagonal pattern with a threefold symmetry of the intensity of the first order diffraction spots is visible for the plasma treated sample (cf. Fig. 6 (a)). This threefold intensity distribution is based on the ABC layer stacking sequence along the ⟨111⟩ directions of the cubic fluorite structure of CeO₂. Furthermore, at several electron energies, the shape of the main spots becomes triangular indicating the formation of tetrahedral pyramids on the ceria surface (see also Ref. 48).

After annealing at 660°C, a (√7 × √7)R19.1° superstructure with two mirror domains appears (cf. Fig. 6 (b)). This superstructure can be attributed to the surface structure of the t-phase (Ce₇O₁₂) of ceria which is based on ordered oxygen vacancies along the ⟨111⟩ directions in the bulk fluorite CeO₂ structure.²² While the intensity of the fundamental diffraction spots stays almost constant, the intensity of the (√7 × √7)R19.1° superstructure spots decreases with higher annealing temperatures.

Applying PDA temperatures in the region of 850°C - 880°C leads to the formation of a (√27 × √27)R30° structure (cf. Fig. 6 (c)). Note, that there is no sharp transition from the (√7 × √7)R19.1° to the (√27 × √27)R30° structure. After annealing at 850°C a superposition of these two patterns is measured but the intensity of the (√7 × √7)R19.1° diffraction peaks is very weak. Thus, both phases coexist for these treatments. Taking into account the XPS results, the (√27 × √27)R30° structure corresponds to a stoichiometry close to Ce₂O₃ with excess oxygen.

After PDA at 880°C, a weak (4 × 4) pattern appears (cf. Fig. 6 (d)) that can be attributed to the bixbyite structure of cub-Ce₂O₃ similar to cub-Pr₂O₃(111) grown on Si(111).⁴⁰,⁴¹ Fig. 6 (f) compares cross section of the diffraction pattern from the (4 × 4) bixbyite structure (upper curve) and the (√27 × √27)R30° structure. These line scans are normalized to the (surface) Brillouin-zone size (BZ) of CeO₂(111) (lateral row distance aCeO₂ = 3.314 Å).

After annealing above 900°C, a sharp (2 × 1) pattern with weak streaks between the fundamental diffraction spots appears (cf. Fig. 6 (e)). This pattern is superimposed with a (√3 × √3)R30° pattern and has been assigned to different surface phases of cerium silicide.⁴²,⁴³ In addition, very weak polycrystalline rings become visible at several electron energies (data not shown). These findings are in good agreement with the XPS results since a strong Si 2p signal (E_{3d}) appears when annealing at temperatures above 900°C (cf. Fig. 4) indicating the segregation of Si to the surface.

A detailed spot profile analysis is performed after each annealing cycle to get deeper insight of the near surface structure and surface morphology. In the following, K₁ and K₂ denote the lateral and vertical components of the scattering vector with respect to the sample surface. Cross-sections (line scans) are measured through the (00)-spot along the [112] direction. The data was fitted with two Lorentzian functions, one sharp and intense component for the central diffraction spot and the other for the appearing broad and weak shoulder due to the triangular reflex shape (cf. Fig. 7 (a)).

The first function has its center at K₁ = 0 (central peak), while the lateral position of the shoulder changes with K₂. This behavior of the shoulder is caused by facets at the film surface.⁴⁴,⁴⁵ The FWHM of the central peak oscillates with K₂ (cf. Fig. 7 (b)) indicating that flat terraces are separated by atomic steps. These oscillations can be fitted by the function

\[ \text{FWHM}(K_{\perp}) = 100\% \cdot \text{BZ} \cdot \text{CeO}_2 \cdot \sqrt{\frac{27}{\pi}} \cdot \frac{1}{\sqrt{\left( \frac{\cos(dK_{\perp})}{\Gamma} \right)}} \]

(1)

according to the model presented in Ref. ⁴⁶,⁴⁷. Here, d denotes the step height and \( \Gamma \) the mean terrace width. Compared

![Fig. 5 XP spectra of the O 1s peak (E_B = 530.2 eV) exhibiting a weak shoulder at E_B ≈ 532 eV. The spectra are normalized to the Ce 3d signal. The FWHM of the O 1s peak increases after annealing above 800°C. The intensity of the O 1s peak is drastically reduced after annealing at 1050°C and the shoulder shifts to higher binding energies indicating Si-O bonds.](image-url)
to Ref.46 the prefactor \(\sqrt{22/3 - 1}\) is needed to describe the isotropic exponentially decaying 2D correlation.

The spot profile analysis for PDA temperatures up to 660°C yields the same results within experimental error (independent of the annealing temperature). An average step height of \(d = (3.09 \pm 0.05) \text{ Å}\) close to the bulk value of CeO\(_2\)(111) crystal plane spacing \(c_{\text{CeO}_2} = 3.124 \text{ Å}\) is determined in accordance with recent studies by non-contact atomic force microscopy48. Furthermore, the average terrace width \(\langle \Gamma \rangle = (6.0 \pm 0.5) \text{ nm}\) does not change significantly in this temperature region. These results are in good agreement with the XRD results described in the following section which also show no change of the bulk structure for low annealing temperatures.

For PDA temperatures above 660°C, the oscillating part of the FWHM curves is strongly diminished indicating the formation of large terraces beyond the resolution of our instrument. The smoothening of the ceria film surface, however, has also been observed in a NC-AFM study on similar films48 with an overall morphology closely resembling that of a (111)-surface of bulk ceria.9,49

3.3 XRD results

Reciprocal space mappings of \(\text{in-situ}\) XRD measurements, as well as, \((00L)\) crystal truncation rods (CTRs) after annealing at different temperatures are presented in Fig. 8 and Fig. 9, respectively. The measurements after each annealing step are performed at RT, too. In the following, the subscripts \(S\) and \(B\) denote surface and bulk coordinates, respectively. The component of the scattering vector \(K_{\perp}\) normal to the surface is scaled to reciprocal lattice units (r.l.u.) of the silicon substrate via \(L = 2\pi K_{\perp}/c_{\text{Si}}\) where \(c_{\text{Si}} = 3.136 \text{ Å}\) denotes the vertical layer spacing of Si(111). Thus, the peaks denoted by \((00L)\) correspond to the \((LLL)\) bulk Bragg peaks.

Fig. 8 shows reciprocal space mappings of the specular \((00L)\)-rod close to the Si(111)\(_B\) Bragg peak which is equiv-
alient to Si(001)$_5$. For the as grown samples, a broad oxide Bragg peak next to the sharp silicon peak is visible at slightly larger $L$ values than Si. This peak can be attributed to CeO$_2$. After annealing at elevated temperatures, further Bragg peaks appear at lower $L$ values due to intermediate ceria phases with reduced oxygen content or cerium silicide. Starting at 850°C elongated features indicating a polycrystalline structure appear at $L = 0.889, 1.089, 1.099$ and 1.128 in the reciprocal space mappings. These structures can not be unambiguously assigned to any cerium silicate (CeSi$_x$O$_y$) or silicide (CeSi$_x$) phase.

CTR scans at $K_{||} = 0$ Å$^{-1}$ of the (00L) CTR are performed for a detailed analysis of the appearing Bragg peaks with results shown in Fig. 9. The untreated sample shows the CeO$_2$(111)$_B$ Bragg peak at $L = 1.005$ corresponding to a vertical layer distance of $c_{\text{CeO}_2} = 3.120$ Å (bulk $c_{\text{CeO}_2} = 3.124$ Å) next to the narrow Si(111)$_B$ peak ($L = 1$). Furthermore, fringes of the praseodymia buffer layer are well discernible due to its very homogeneous thickness. These fringes do not change for all PDA treatments at temperatures below or equivalent to a temperature of 650°C. For treatments at higher temperatures, the fringes are diminished due to a roughening of the buffer layer or a reaction between the ceria film and praseodymia buffer layer.

The Bragg peak corresponding to the praseodymia buffer layer is shifted to lower $L$ values than expected for hex-Pr$_2$O$_3$(0001)$_B$ peak ($L = 1.044$) indicating an oxidation of the buffer layer during ceria growth. In addition, no Bragg peaks attributed to hex-Pr$_2$O$_3$(0001) at $L = 0.522$ and 1.566 were observed (not shown here). Thus, the praseodymia buffer layer has transformed to a cubic structure due to the additional oxygen content supplied by the ceria film. An accurate determination of the position of the praseodymia Bragg peak is very difficult due to its weak intensity in comparison with the high intensity of the close Si(111)$_B$ Bragg peak. An estimation can be made using a simulation within the kinematic diffraction theory. The results of such simulations point to a $L$ value between cub-Pr$_2$O$_3$(222)$_B$ ($L = 0.974$) and Pr$_6$O$_{11}$(111)$_B$ ($L = 0.997$). Hence, we assume an oxidation of the buffer layer during growth in contrast to the growth of thinner ceria films on a hex-Pr$_2$O$_3$(0001) buffer layer reported previously.

After applying PDA temperatures of 650°C and 700°C, further diffraction peaks appear at $L = 0.982$ and $L = 0.988$, respectively. Since the intermediate phases are based on the fluorite type CeO$_2$ lattice with ordered oxygen vacancies, the stoichiometry CeO$_x$ can be determined using the concept of the pseudo-cubic lattice parameter predicting the linear relationship

$$x = -3.945\text{Å}^{-1} \cdot c + 14.329,$$

between the stoichiometry parameter $x$ and the layer distance $c$ as shown in Fig. 10. Therefore, the peaks of the intermediate phases can be attributed to the $t$ (Ce$_7$O$_{12}$) and $d$ (Ce$_{11}$O$_{20}$) phases of ceria having the layer spacings of $c_{\text{Ce}_7\text{O}_{12}} = 3.193$ Å and $c_{\text{Ce}_{11}\text{O}_{20}} = 3.174$ Å, respectively. The larger layer distances of the reduced phases results from the Ce$^{4+} \rightarrow$ Ce$^{3+}$ transition yielding a larger ion radius. Note, the pseudo-cubic lattice parameter are based on the bulk structures of ceria and do not consider any strain effects which may appear in thin films. For the film studied here, the intensity of the Ce$_7$O$_{12}$(111)$_B$ and Ce$_{11}$O$_{20}$(111)$_B$ peaks increases with increasing PDA temperature.

Furthermore, the Ce$_7$O$_{12}$(111)$_B$ and Ce$_{11}$O$_{20}$(111)$_B$ peaks disappear when the XRD measurements are carried out at elevated temperatures and reappear after the sample is cooled.
Fig. 8 Reciprocal space mappings close to the Si(111) Bragg peak obtained for annealing at different temperatures. The measurements are performed at RT. After annealing above 850 °C, elongated features pointing to a polycrystalline structure appear at $L = 0.89, 1.09, 1.10$. (results not shown) while the CeO$_2$(111)$_B$ peak does not vanish at these temperatures. Possible explanations for this temperature related behavior are a high Debye-Waller factor or an order-disorder transition due to the high mobility of lattice oxygen at high temperatures. The latter effect leads also to a disordered arrangement of oxygen vacancies and subsequent loss of the superstructure. On the other hand, the CeO$_2$(111)$_B$ peak shifts to lower $L$ values (corresponding to higher layer distances) as expected due to thermal expansion when measured at elevated temperatures.

The reason for the smaller layer distance of the CeO$_2$ film in comparison to the bulk structure (cf. Fig. 11 (a)) for low PDA temperatures is tensile lateral strain based on the lattice mismatch between the CeO$_2$(111) film and the praseodymia buffer layer. With increasing PDA temperature the CeO$_2$(111)$_B$ peak shifts to larger $L$ values (smaller layer distances) while the Ce$_7$O$_{12}$(111)$_B$ and Ce$_{11}$O$_{20}$(111)$_B$ peak positions do not change significantly (cf. Fig. 9 and Fig. 11 (a)). Assuming a tetragonally distorted film with biaxial in-plane strain $\Delta a$, the lateral layer distance $a$ of the appearing phases can be determined using the relation

$$\frac{\Delta a}{a_{\text{bulk}}} = -\frac{1 - v}{2v} \frac{\Delta c}{c_{\text{bulk}}}$$

as derived by Hashimoto et al., where $v \approx 0.3$ is the Poisson ratio of CeO$_2$. The CeO$_2$ Poisson ratio is used for the calculations of all appearing phases since values of the Poisson ratio for the intermediate phases are not available in literature. The occurring error can be neglected since the structures of the intermediate phase are dominated by the cation sublattice which does not change significantly during reduction. The results for the lateral layer distance of the three phases is presented in Fig. 11 (b). With increasing PDA temperature, the calculated lateral layer distance of CeO$_2$ shifts to higher values. Hence, the tensile strain of the remaining CeO$_2$(111) film is increased with higher temperatures. PDA treatments above 700°C do not change the lateral layer distances of the Ce$_7$O$_{12}$ and Ce$_{11}$O$_{20}$ phase. In comparison with the bulk values, the
Ce$_2$O$_{12}$ exhibits strain similar to the CeO$_2$ phase while the Ce$_{11}$O$_{20}$ phase is fully relaxed.

After a PDA treatment at 900°C, the three oxide peaks described above vanish and are replaced by peaks at $L = 0.972$, $L = 0.959$ and $L = 0.944$ (cf. Fig. 9). The peak at $L = 0.972$ corresponds to a vertical layer distance of $c_{\text{Ce}_2\text{O}_3} = 3.226$ Å and can be attributed to the cub-Ce$_2$O$_3$(222)$_b$ Bragg peak of the bulk bixbyite phase of Ce$_2$O$_3$ (bulk $c_{\text{cub-Ce}_2\text{O}_3} = 3.222$ Å). Thus, the different oxide phases are transformed into the ceria phase of lowest oxygen content. In addition, no Bragg peaks of the hexagonal Ce$_2$O$_3$ phase ($L = 0.518, 1.036, 1.554, etc.$) are observed. Thus, the cubic phase of Ce$_2$O$_3$ is formed exclusively.

The peak at $L = 0.959$ corresponds to a layer distance of $c_{\text{Ce}_2\text{O}_3(s)} = 3.270$ Å and can be attributed to a strained cub-Ce$_2$O$_3$ film$^{10}$. In comparison with the bulk value of Ce$_2$O$_3$, this vertical layer distance is 1.36% larger indicating a compressive lateral strain based on the lateral lattice mismatch of cub-Ce$_2$O$_3$(111) with respect to Si(111) (+2.70%).

Furthermore, the peak at $L = 0.944$ can not be assigned to any ceria phase and exhibits a larger periodicity ($L = 0.472, 0.944, 1.416, etc.$), resulting in a layer distance of $c = 6.642$ Å. Taking into account the surface sensitive LEED and XPS measurements, we attribute this peak to the hex-CeSi$_{1.67}$(0002)$_b$ Bragg peak of the hexagonal CeSi$_{1.67}$ phase proposed by Manke et al.$^{42}$.

**Fig. 9** Specular (00$L$) XRD scans close to the Si(111)$_b$ Bragg peak of the substrate. The samples are annealed at temperatures up to 900°C for 30 min. After each temperature step, the samples are cooled to RT and the measurements are performed. The as grown sample shows only the CeO$_2$(111) peak next to the substrate. At temperatures above 600°C and 650°C peaks attributed to Ce$_7$O$_{12}$(111) and Ce$_{11}$O$_{20}$(111) appear, respectively. Thereafter, silicide and silicate peaks appear at temperatures above 800°C. The observed fringes correspond to the underlying praseodymia buffer layer. The Bragg peak of the buffer layer seems shifted to $L$ values close to the cub-Pr$_2$O$_3$(222)$_b$ peak rather than the expected for hex-Pr$_2$O$_3$(0002)$_b$ peak (dashed lines). Therefore, an oxidation of the praseodymia layer during growth is assumed.

XRD measurements reveal that not the entire film is reduced since the CeO$_2$(111) film and the CeO$_2$ crystallites or at the interface region close to the silicon substrate. In the latter case, similar to the growth of the CeO$_2$(111) films, oxygen has to be transported into the substrate resulting in the formation of amorphous SiO$_2$ at the interface between film and substrate. We assume that a lower diffusion rate of oxygen into the substrate in comparison to the oxygen desorption at the surface is responsible for the formation of the Ce$_{11}$O$_{20}$ phase at the interface between film and substrate. This assumption is supported by the vanishing of the fringes due to the praseodymia buffer layer in the XRD measurements (cf. Fig. 9). This indicates an interface reaction, e.g. roughening of the praseodymia interface or an intermixing of the praseodymia and ceria films at temperatures above 650°C. In addition, the tensile strain of the CeO$_2$ film increases with higher annealing temperatures. Possible reasons for the increasing strain are the lateral lattice mismatch between Ce$_{11}$O$_{20}$(111) and CeO$_2$(111) or the strong thermal expansion of the CeO$_2$(111) at elevated temperatures. Thus, more research has to be done to elucidate the role of the interface.

Comparing the diffraction measurements with the XPS results, a temperature offset for the formation of the t-phase (Ce$_7$O$_{12}$) is observed. This phase is formed at 660°C if the sample is heated via resistive heating as done for the XRD and SPA-LEED experiments. On the contrary, the t-phase confirmed by conventional LEED setup is formed in the XPS experiments at $\approx$ 800°C when annealed via filament heating. We can exclude an experimental error in temperature control since the Ce$_2$O$_3$ phase with the lowest oxygen content and the silicide are formed at the same temperatures in both experimental setups. Thus, a possible explanation for the offset are the different cooling rates based on the experimental setup. Hence, we assume that for an annealing time of 30 min used in our experiments, the samples were not in the thermodynamical equilibrium. For the lower cooling rates (XPS experiments), oxygen from deeper layers of the oxide film diffuses to the surface since the oxide films is exposed to higher temperatures for longer times compared to the diffraction experiments. Hence, the formation of the superstructure received at high annealing temperatures is modified during the cooling process due to re-oxidation. We conclude that the cooling rate has a strong impact on the formation of the superstructures.

The XRD measurements show that polycrystalline Ce$_{11}$O$_{20}$ or Ce$_{11}$ phases are formed after annealing at 850°C which can not be attributed to any known cerium silicate or silicide. This phase becomes more pronounced at 900°C and is also detected at the surface via SPA-LEED. In addition, a single crystalline cerium silicide (CeSi$_{1.67}$) is detected in the SPA-LEED and XRD studies.

The results from the XRD and SPA-LEED measurement...
clearly reveal the appearing Ce$_2$O$_3$ phase has a bixbyite structure (cub-Ce$_2$O$_3$). This is in contrast to bulk single crystals where the hexagonal phase (hex-Ce$_2$O$_3$) is the most stable.$^{53,54}$ Hence, the silicon substrate has a stabilization effect on the cub-Ce$_2$O$_3$ phase.

Furthermore, SPA-LEED measurements show a $\sqrt{2\times 2\sqrt{7}}$R30° superstructure appearing in a very narrow region of PDA temperatures close to the temperature for the transition to cub-Ce$_2$O$_3$. Different to the $\ell$ phase, this diffraction pattern can not be attributed to the surface termination of any well known bulk phase of ceria stable at room temperature and Thus, we assume a film with stoichiometry close to Ce$_2$O$_3$ is stabilized at the near surface region.

Moreover, it should be mentioned that the color of the sample changes from purple (RT) to cyan (890°C) during the PDA treatment. Above a PDA temperature of 900°C the sample turns mat gray due to the silicide formation (see also Ref.$^{48}$). After a few minutes at a temperature of 930°C parts of the sample become metallic luster while the current needed for the resistive heating increases drastically.

5 Conclusion

In this study the influence of PDA on the structure and surface stoichiometry were investigated for a thin ceria film (250 nm) grown on a hex-Pr$_3$O$_5$\((001)/$Si(111) system. It was shown that several crystalline phases with long range ordered oxygen vacancies can be stabilized which may be used for magnetic and catalytic applications in the future. Furthermore, it was revealed that the bulk and surface exhibit a different behavior during reduction. The XRD measurements reveal that higher oxidized phases are still present in the bulk of the film while the oxygen content at the surface is continuously reduced as shown by XPS and SPA-LEED. In addition, it is clearly shown that fully reduced ceria films (Ce$_2$O$_3$) exhibit bixbyite structure if grown on Si(111). PDA treatments at very high temperatures lead to the formation of polycrystalline silicate and crystalline silicide.
