Föhringer Ring 6, 80805 Munich, Germany

A measurement of the longitudinal structure function $F_L(x,Q^2)$ derived from inclusive deep inelastic neutral current $ep$ scattering cross section measurements at high negative four-momentum transfer squared, $35 \leq Q^2 \leq 800$ GeV$^2$, is presented. The data were taken in 2007 with the H1 detector at HERA at a positron beam energy of 27.5 GeV and proton beam energies of 920, 575 and 460 GeV. The measurements of the NC cross sections from this analysis, combined with the reported earlier NC cross section measurements for the same data periods at medium $Q^2$ ($12 \leq Q^2 \leq 90$ GeV$^2$), allowed to measure $F_L(x,Q^2)$ in the range $12 \leq Q^2 \leq 800$ GeV$^2$ and Bjorken-x $0.00028 \leq x \leq 0.0033$. The measured longitudinal structure function is found to be consistent with NLO/NNLO QCD predictions.

1 Introduction

The inclusive deep inelastic (DIS) neutral current (NC) $ep$ scattering cross section at low negative four-momentum transferred squared, $Q^2$, can be written in reduced form as

$$\sigma_r(x,Q^2, y) = \frac{d^2\sigma}{dx dy Q^2} \cdot \frac{Q^4}{2\pi\alpha^2[1+(1-y)^2]} = F_2(x,Q^2) - \frac{y^2}{1+(1-y)^2} \cdot F_L(x,Q^2).$$

(1)

Here, $\alpha$ denotes the fine structure constant, $x$ is the Bjorken scaling variable and $y$ is the inelasticity of the scattering process related to $Q^2$ and $x$ by $y = Q^2/2s$, where $s$ is the centre-of-mass energy squared of the incoming electron and proton.

The cross section is determined by two independent structure functions, $F_2$ and $F_L$. They are related to the $\gamma^*p$ interaction cross sections of longitudinally and transversely polarised virtual photons, $\sigma_L$ and $\sigma_T$, according to $F_2 \propto (\sigma_L + \sigma_T)$ and $F_L \propto \sigma_L$, therefore $0 \leq F_L \leq F_2$. $F_2$ is the sum of the quark and anti-quark $x$ distributions weighted by the electric charges of quarks squared and contains the dominant contribution to the cross section. In the Quark Parton Model the value of the longitudinal structure function $F_L$ is zero, whereas in Quantum Chromodynamics (QCD) it differs from zero due to gluon and (anti)quark emissions. At low $x$ the gluon contribution to $F_L$ exceeds the quark contribution and $F_L$ is a direct measure of the gluon $x$ distribution.

The longitudinal structure function, or equivalently $R = \sigma_L/\sigma_T = F_L/(F_2 - F_L)$, was measured previously in fixed target experiments and found to be small at large $x \geq 0.2$, confirming the spin 1/2 nature of the constituent quarks in the proton. From next-to-leading order (NLO) and NNLO[2] QCD analyses of the inclusive DIS cross section data [3, 4, 5], and from experimental $F_L$ determinations by H1 [6, 7], which used assumptions on the behaviour of $F_2$, the longitudinal structure function $F_L$ at low $x$ is expected to be significantly larger than zero. A direct, free from theoretical assumptions, measurement of $F_L$ at HERA, and its comparison with predictions derived from the gluon distribution extracted from the $Q^2$ evolution of $F_2(x,Q^2)$, thus represents a crucial test on the validity of the perturbative QCD framework at low $x$.

Figure 1: Reduced cross section measured at different proton beam energies of 920, 575 and 460 GeV as a function of $x$ at fixed values of $Q^2$ (left) and at fixed values of $x$ and $Q^2$ as a function of $y^2/[1 + (1 - y)^2]$ for measurements which include both the LAr and Spacial data (right). The lines in the right figure show the linear fits used to determine $F_L(x, Q^2)$.

2 Data Analysis

The model independent measurement of $F_L$ requires several sets of NC cross sections at fixed $x$ and $Q^2$ but different $y$. This was achieved at HERA by variation of the proton beam energy.

The measurements of the NC cross sections presented in this paper are performed in the high $Q^2$ range from 35 to 800 GeV$^2$, using $e^+p$ data collected in 2007 with the H1 detector with a positron beam energy $E_e = 27.5$ GeV and with three proton beam energies: the nominal energy $E_p = 920$ GeV, the smallest energy of 460 GeV and an intermediate energy of 575 GeV. The corresponding integrated luminosities are 46.3 pb$^{-1}$, 12 pb$^{-1}$ and 6.2 pb$^{-1}$. The measurements at high $Q^2$ are performed with the positrons scattered into the acceptance of the Liquid Argon calorimeter (LAr), which corresponds to the polar angle range of the scattered positron $\theta_e \lesssim 153^\circ$.

The sensitivity to $F_L$ is largest at high $y$ as its contribution to $\sigma_r$ is proportional to $y^2$. The high reconstructed $y$ values correspond to low values of the scattered positron energy $E'_e$:

$$y = 1 - \frac{E'_e}{E_e} \sin^2(\theta_e/2), \quad Q^2 = \frac{E'_e^2 \sin^2 \theta_e}{1 - y}, \quad x = Q^2/sy. \quad (2)$$

The scattered positron is identified as a localised energy deposition (cluster) with energy $E'_e > 3$ GeV in the LAr calorimeter. This corresponds to the inelasticity range up to $y \approx 0.9$. The NC events are triggered on positron energy depositions in the LAr calorimeter, on hadronic final state energy depositions in the backward Spacial calorimeter ($\theta \gtrsim 153^\circ$), and using a new trigger hardware commissioned in 2006. This new trigger system includes the...
Jet Trigger, which performs a real time clustering in the LAr, and the Fast Track Trigger (FTT), which utilizes on-line reconstructed tracks in the central tracker (CT). The combined trigger efficiency reaches 97% at $E_t = 3$ GeV and $\approx 100\%$ at $E_t > 6$ GeV. To ensure a good reconstruction of kinematical properties, the reconstructed event vertex is required to be within 35 cm around the nominal vertex position along the beam axis. The primary vertex position is measured using tracks reconstructed in the central tracker system. The positron polar angle is determined by the positions of the interaction vertex and the positron cluster in the LAr calorimeter.

Small energy depositions in the LAr caused by hadronic final state particles can also lead to fake positron signals. The large size of this background, mostly due to the photoproduction process at $Q^2 \approx 0$, makes the measurement at high $y$ especially challenging. This background is reduced by the requirement to have a track from the primary interaction pointing to the positron cluster in the LAr with an extrapolated distance to the cluster below 12 cm. At $E_t < 6$ GeV further requirements, small transverse energy weighted radius of the cluster (Ecra < 4 cm) and matching between the energy of the cluster and the track momentum ($0.7 < E_t/|P_{track}| < 1.5$), are applied. Further suppression of photoproduction background is achieved by requiring longitudinal energy-momentum conservation $\Sigma_e(E_e - p_{e,i}) > 35$ GeV, where the sum runs over the energy and longitudinal momentum component of all particles in the final state including the scattered positron. For genuine, non-radiative NC events it is approximately equal to $2E_e = 55$ GeV. This requirement also suppresses events with hard initial state photon radiation. QED Compton events are excluded using a topological cut against two back-to-back energy depositions in the calorimeters.

In addition, a method of statistical background subtraction is applied for the $E_p = 400$ and 575 GeV data at high $y$ ($0.38 < y < 0.90$ and $E_t < 18$ GeV). The method relies on the determination of the electric charge of the positron candidate from the curvature of the associated track. Only candidates with right (positive) sign of electric charge are accepted. The photoproduction background events are about equally shared between positive and negative charges. Thus, selecting the right charge the background is suppressed by about a factor of two. The remaining background in the accepted events is corrected for by statistical subtraction of background events with the wrong (negative) charge from the right sign event distributions. This subtraction procedure requires a correction for a small but non-negligible charge asymmetry in the background events due to enlarged energy depositions in the annihilation of anti-protons in the LAr calorimeter.

The small photoproduction background for the 920 GeV data ($y < 0.56$) is estimated and subtracted using a PYTHIA simulation normalised to the photoproduction data tagged in the electron tagger located downstream of the positron beam at 6 m.

3 The NC Cross Section and $F_L(x, Q^2)$ Measurements

The reduced NC cross sections are measured at high $Q^2$, $35 \lesssim Q^2 \lesssim 800$ GeV$^2$, in the range $0.1 \leq y \leq 0.56$ for the $E_p = 920$ GeV data and $0.1 \leq y \leq 0.9$ for the 400 and 575 GeV data. The measurements are shown in figure 1 (left) together with the ones at medium $Q^2$ [8], $12 \lesssim Q^2 \lesssim 90$ GeV$^2$, obtained for the same data periods using the Spacial calorimeter for the measurement of the scattered positron with $\theta_e \gtrsim 153^\circ$. At $Q^2 \gtrsim 120$ GeV$^2$ the measurements are entirely from the LAr analysis. In the range $35 \leq Q^2 \leq 90$ GeV$^2$ the cross section is measured at $E_p = 400(920)$ GeV in the LAr (Spacial) analysis and for the $E_p = 575$ GeV data the cross section is obtained either using the LAr or Spacial. Small,
Figure 2: The $F_L(x,Q^2)$ measurement as a function of $x$ at fixed values of $Q^2$. The inner and outer error bars are the statistical and total errors, respectively. The curve represents the NLO QCD prediction derived from the H1 PDF 2000 fit to previous H1 data.

1-2%, relative normalisation corrections to the cross sections at $E_p = 460, 575$ and 920 GeV, common for both analyses, are derived using measurements at low $y$ and applied to the cross section points shown in the figure. In this low $y$ region, the cross sections are determined by $F_2(x,Q^2)$ only, apart from a small correction for residual $F_L$ contribution.

The data at lower $E_p$ and the same $Q^2$ and $x$ cover the higher $y$ region. The longitudinal structure function is extracted from the slope of the measured reduced cross section versus $y^2/[1+(1-y)^2]$. This procedure is illustrated in figure 1 (right) for $Q^2$ and $x$ values, where both the LAr and Spacial measurements are available. The measurements are consistent with the expected linear dependence, demonstrating consistency of the two independent analyses, which utilize different detectors to measure the scattered positron.

The central $F_L(x,Q^2)$ values are determined in straight-line fits to the $\sigma_T(x,Q^2,y)$ measurements with statistical errors better than 10%, using the statistical and uncorrelated systematic errors added in quadrature. Statistical and total $F_L$ errors are determined in the fits using statistical and total errors, respectively. The uncertainty due to the relative normalisation of the cross sections is added in quadrature to the total $F_L(x,Q^2)$ error. This uncertainty is estimated from an effect of the 1% variation of the normalisation of the 920 GeV cross section on a fit result. The measurement of $F_L(x,Q^2)$ limited to $Q^2$ and $x$ values, where the total $F_L$ error is below 0.4 (1.1) for $Q^2 \leq 35 (> 35)$ GeV$^2$, is shown in figure 2. The result is consistent with the NLO QCD prediction based on the H1 PDF 2000 fit [7] performed using previous H1 cross section data at nominal proton energy.
The $F_L(Q^2)$ values averaged over $x$ at fixed $Q^2$ are presented in figure 3. The average is performed using the total errors of individual measurements. The overall correlated component for the averaged $F_L$ is estimated to vary between 0.05 and 0.10. The averaged $F_L$ is compared with the H1 PDF 2000 fit [7] and with the expectations from global parton distribution fit at NNLO (NLO) perturbation theory performed by the MSTW [3] (CTEQ [4]) group and from the NNLO QCD fit by Alekhin [5] (see also figures in [9]). Within the experimental uncertainties the data are consistent with these predictions.

4 Summary

The measurement of the longitudinal proton structure function in deep inelastic scattering at low $x$ is presented. The $F_L$ values are extracted from three sets of cross section measurements at fixed $x$ and $Q^2$, but different inelasticity $y$ with three different proton beam energies at HERA. For the covered $Q^2$ range between 12 and 800 GeV$^2$, the $F_L$ results are consistent at the current level of accuracy with the DGLAP evolution framework of perturbative QCD at low $x$.
