(Rceived 8 May 2010; revised manuscript received 27 July 2010; published 7 September 2010)

Hard x-ray scattering experiments with a photon energy of 100 keV were performed as a function of temperature and applied magnetic field on selected compounds of the \( \text{RFe}_3(\text{BO}_3)_4 \) family. The results show the presence of several diffraction features, in particular, nonresonant magnetic reflections in the magnetically ordered phase and structural reflections that violate the diffraction conditions for the low-temperature phase \( P3_121 \) of the rare-earth iron borates. The temperature and field dependence of the magnetic superlattice reflections corroborate the magnetic structures of the borate compounds obtained by neutron diffraction. The detailed analysis of the intensity and scattering cross section of the magnetic reflection reveals details of the magnetic structure of these materials such as the spin domain structure of \( \text{NdFe}_3(\text{BO}_3)_4 \) and \( \text{GdFe}_3(\text{BO}_3)_4 \). Furthermore we find that the correlation length of the magnetic domains is around 100 Å for all the compounds and that the Fe moments are rotated \( 53°\pm3° \) off from the hexagonal basal plane in \( \text{GdFe}_3(\text{BO}_3)_4 \).

I. INTRODUCTION

The family of rare-earth compounds with the chemical formula \( \text{RFe}_3(\text{BO}_3)_4 \) (R=rare earth or Y) has triggered a considerable attention in the last few years. From a fundamental point of view, already the presence of two different magnetic ions (3d and 4f elements) which form two interacting magnetic sublattices, suggests a subtle interplay of complex magnetic ground states. In addition, a rich variety of interesting structural and dielectric properties has been observed in these materials, partially coupled to the systems’ magnetism, which is evidenced by a plethora of structural and magnetic phase transitions which depend on the rare-earth ion.1–8 Furthermore, magnetoelectric coupling and multiferroic features, i.e., the coexistence of elastic, magnetic, and electric order parameters have been reported for the Nd- and Gd-based compounds.8–13

At room temperature \( \text{RFe}_3(\text{BO}_3)_4 \) compounds crystallize in the space group \( R32.12 \). For “light” rare-earth ions from La to Sm, this structure is kept until low temperatures. “Heavier” rare-earth ions from Eu to Yb, and also Y cause a symmetry reduction to space group \( P3_21 \) upon lowering temperature which is manifested as a sharp peak at the transition temperature in specific-heat measurements.1,3,13 The transition temperature \( T_S \) depends basically on the size of the \( R \)-type ion present in the structure and one observes a decreasing \( T_S \) by increasing the \( R \) radius. In particular, one finds \( T_S=201.5 \text{ K}, 155 \text{ K}, \) and \( 445 \text{ K} \) for the Tb-, Gd-, and Y-based compounds, respectively.6 Note, that \( \text{NdFe}_3(\text{BO}_3)_4 \) does not undergo the symmetry reduction and remains in the \( R32 \) space group. The main elements of the crystal structure of the high-symmetry \( R32 \) phase are spiral chains of edge-sharing \( \text{FeO}_6 \) octahedra running along the \( c \) axis. Each rare-earth ion is coordinated by six oxygen ions forming a trig-
Recently GdFe$_3$(BO$_3$)$_4$ and NdFe$_3$(BO$_3$)$_4$ have been reported to exhibit a significant magnetodielectric coupling.\textsuperscript{9,10} For electric polarization to appear, small distortions or displacements of the atoms from their symmetry position are necessary. Therefore for the magnetically induced polarization present in these samples, a lattice distortion is expected which has not yet been seen experimentally. Magnetostriiction measurements\textsuperscript{5,10} have shown a clear relation between lattice and magnetoelectric properties, but a proper description of the lattice distortions that produce the observed polarization is still lacking. In recent neutron-scattering investigations which confirm the above described spin structures, no new information is obtained regarding structural displacements which would explain the observed electric polarization, mainly due to the low $q$ resolution of neutrons as compared to x rays. Moreover it is not clear if the observed superstructures are purely magnetic or also structural. In this respect detailed x-ray diffraction studies are necessary to elucidate small structural and magnetic features.

In this paper we present a comprehensive hard x-ray scattering study on RFe$_3$(BO$_3$)$_4$ with R=Gd, Tb, Nd, and Y in order to better understand the structural and magnetic properties of the material. Our data reveal a weak superstructure reflection at $(0,0,3/2 \pm 1.5)$, i.e., at the antiferromagnetic ordering vector seen in neutron scattering. This reflection is clearly correlated with an in-plane ordering of the Fe spins and—depending on the material—can thus be induced by an external magnetic field. Through a careful analysis of the $q$ dependence of this reflection we rule out that it is related to a distortion of the lattice and demonstrate its purely magnetic character. Detailed analysis of the integrated intensities of the Bragg and superlattice reflections, together with their scattering cross section, allows us to determine the size of the spin component of the magnetic moments which are perpendicular to the scattering plane and their relative orientation with respect to the hexagonal basal plane. Moreover, in the earlier reported $P3_1 21$ low-symmetry structural phase we observe additional reflections at $(0,0,3/2 \pm 1)$ that violate the diffraction conditions of $P3_1 21$ and thus are suggestive of an overlooked symmetry reduction when indexing the crystal structure or the appearance of a structural distortion that induces a lattice modulation.

The paper is organized as follows. In Sec. II a short introduction into x-ray magnetic scattering (XMS) is given followed by a discussion of the nonresonant scattering cross section of x rays by magnetic materials at high photon energies, in the frame of our experimental setup. Experimental details are given in Sec. III while the results of the observations and their discussion are presented in Sec. IV. This section is divided in two parts. One concerns the structural phase transition while the second part focuses on the magnetic ordering of the system, which causes a superlattice peak with Miller indices $(0,0,1.5)$. The nature of which is demonstrated to be magnetic. Finally the work is summarized in Sec. V.

II. X-RAY MAGNETIC DIFFRACTION

Neutron diffraction has been, since the determination of the magnetic structure of MnO by Shull et al.,\textsuperscript{23} the primary tool for revealing the magnetic structure of magnetic materials. The main reason for this is the direct interaction between the neutron dipolar moment with the atomic magnetic moment of the sample. The cross section of this is comparable with the neutron-nuclei interaction, and thus explains comparable intensities of magnetic and nuclear reflections. On the other hand the intensity of an x-ray beam scattered by unpaired electrons in a sample is much smaller than pure charge scattering by a significant factor\textsuperscript{24} as is demonstrated in the following equation:

$$\frac{\sigma_{\text{mag}}}{\sigma_{\text{charge}}} = \frac{\hbar}{m c^2} \frac{N_m^2}{N^2} \frac{\langle s \rangle^2 f^2}{f} \sim 10^{-6}$$

with $N_m$ the number of magnetic electrons per atom, $N$ the number of electrons per atom, $f_m$ and $f$ are the magnetic and charge form factors, respectively. $\langle s \rangle$ is the expectation value of the spin quantum number and $\hbar \omega$ and $mc^2$ are the photon energy and electron’s rest mass, respectively. Apart from using resonant XMS (RXMS), which has advanced to become a very successful tool in the past years,\textsuperscript{25-27} one can overcome this difference in intensities only by using high brilliance, collimated and polarized sources like synchrotron radiation. This so-called nonresonant XMS (NRXMS) has only
rarely been applied in the past years to study magnetic structures.\textsuperscript{28-31} However, compared to neutron scattering this technique offers some advantages since it is possible to separate spin and angular momenta since the reference frame as defined in Ref. 29. Note that different ways on the scattering geometry, photon energy, and initial and final polarization states of the x-ray beam, as will be discussed in detail below.

Nonresonant x-ray magnetic scattering cross section

Out of various discussions of the nonresonant cross section of x-ray magnetic scattering\textsuperscript{29,30,32} we follow the one of Brückel\textit{ et al.}\textsuperscript{29} The elastic cross section for scattering of photons with initial incident polarization $\varepsilon$ and final polarization $\varepsilon'$ can be written as

$$\frac{d\sigma}{d\Omega} \bigg|_{\varepsilon \rightarrow \varepsilon'} = r_e^2 \left| (M_C)_{\varepsilon' \varepsilon} + i \frac{\lambda_i}{d} (M_M)_{\varepsilon' \varepsilon} \right|^2,$$

where $r_e$ is the electron classical radius and $\lambda_i$ is the Compton length of the electron. The matrices $(M_M)$ and $(M_C)$ describe the polarization dependence of the magnetic and charge scattering amplitudes, respectively. Figure 2 depicts the reference frame for the diffraction experiments performed in this work. Here, $k$ and $k'$ refer to the incoming and outgoing x-ray beams, respectively. The $\sigma$ and $\pi$ vectors correspond to polarization perpendicular and parallel to the scattering plane. Finally, $\hat{u}_1$, $\hat{u}_2$, and $\hat{u}_3$ are the unitary vectors of the reference frame as defined in Ref. 29. Note that $\hat{u}_3$ is parallel to $k-k'=q$, which defines the scattering vector. If we only consider pure magnetic diffraction $(M_C)=0$, in the frame sketched in Fig. 2, and taking into account that our diffraction measurements were performed with $\pi$-polarized incoming photons (see Fig. 2) at an energy of 100 keV ($\lambda=0.1239\ \text{Å}$). The matrix that describes the magnetic scattering amplitude $(M_M)$ reduces to\textsuperscript{30}

$$\left( \begin{array}{c} \sigma \\ \pi \end{array} \right) = \left( \begin{array}{cc} S_2 & 0 \\ 0 & S_2 \end{array} \right) \left( \begin{array}{c} \sigma' \\ \pi' \end{array} \right),$$

where $S_2$ is the projection of the spin moment in the $\hat{u}_2$ direction. This means that under high-energy diffraction conditions, nonresonant magnetic reflections can be observed at positions of the reciprocal space where no charge scattering is present, if the spin moments of the atoms have a component perpendicular to the x-ray scattering plane. Note that the incoming/outgoing beam polarization plays no role for the analysis of the diffracted intensities. Therefore, the cross section of a pure magnetic reflection under the above discussed conditions has the following form:

$$\frac{d\sigma}{d\Omega}_m = r_e^2 \left| \left( \begin{array}{c} \lambda_i \\ d \end{array} \right) \right|^2 |S_2|^2.$$

III. EXPERIMENTAL DETAILS

Single crystals of $R\text{Fe}_5(\text{BO}_3)_4$ with $R=\text{Y, Nd, Gd, and Tb}$ have been grown using a $K_2\text{Mo}_5\text{O}_{10}\text{O}_{10}$-based flux\textsuperscript{30,33} and characterized by specific-heat and magnetic-susceptibility measurements using a physical property measurement system and a superconducting quantum interference device magnetometer, respectively, from Quantum Design.\textsuperscript{33,34} High-energy x-ray diffraction experiments were performed at beamline BW5 in Hamburg (HASYLAB at DESY) using an incident photon energy of 100 keV. The penetration depth of the x rays at this energy is on the order of millimeters, enabling the study of bulk properties of large single crystals. The triple-axis diffractometer is equipped with a cryomagnet mounted on a double-tilt table with eulerian geometry and a solid-state Ge detector (energy resolution of 500 eV at 100 keV).\textsuperscript{35} The sample was mounted inside the cryomagnet where temperatures down to 1.5 K can be reached and horizontal magnetic fields up to 10 T can be applied parallel and perpendicular to the scattering vector. The samples were aligned with the horizontal scattering plane being perpendicular to the $ab$ plane of the samples. Magnetic fields up to 8 T were applied along the $c$ direction and perpendicular to it.

The full integrated intensity of the observed reflections was extracted from the raw data by performing reciprocal lattice scans (e.g., $l$ scans) at a given reflection, followed by scans along the $\omega$ direction at the maximum intensity of the former scan. The $l$ and $\omega$ scans were made extended to the peak sides until a constant background was reached. The scans were fitted using a Gaussian profile.

IV. RESULTS AND DISCUSSION

A. Structural transition at $T_S$

In order to search for superlattice reflections in our diffraction experiments, we performed overview scans along $(0,k,0)$ with $0.45<k<2.9$ and along $(0,0,l)$ with $0.9<l<2.9$ at various temperatures. Figure 3(a) shows a representative example of the $(0,0,l)$ scan for $\text{TbFe}_5(\text{BO}_3)_4$ at low temperature (2 K) and at 212 K [Fig. 3(a) insets], i.e., in the reported $R32$ and $P3\bar{1}21$ symmetries of the crystal structure, respectively. Along this direction, the reflection conditions of both symmetries are identical, viz., $(0,0,3l)$ with integer $l$. As can be seen in the figure, the reflection conditions for the high-symmetry space group $R32$ are
fectly fulfilled. Interestingly, this is not the case for the low-
temperature data, where clear superlattice peaks at (0,0,1) and
(0,0,2) are observed, thus violating the reflection condi-
tions of the P3121 space group.

We have studied the temperature dependence of these two
unexpected reflections in comparison with the (0,0,3) Bragg
peak in detail as is shown in Fig. 4. The data shown in part
(a) of the figure clearly reveal that the new superlattice peaks
appear abruptly at the structural transition temperature
$T_S = 201.5$ K which is accompanied by a pronounced peak in
the specific heat $c_p$ [cf. Fig. 4(b)]. Upon lowering the tem-
perature, both reflections persist down to the lowest investi-
gated temperature, where both peak intensities gradually in-
crease without significant further changes, suggesting a
stabilization of the structural distortion. The compound un-
dergoes antiferromagnetic order at $T_N = 39$ K as is eviden-
ted$^3$ by a further anomaly in the specific heat and a
rapid decrease in the magnetic susceptibility [cf. Fig. 4(c)].
However, no significant change in the peak intensities occurs
when crossing through this temperature. The occurrence of
these new, in the P3121 symmetry, forbidden reflections at
(0,0,3/1 ± 1) is not a particular feature of TbFe$_3$(BO$_3$)$_4$, but it
is a common feature of all RFe$_3$(BO$_3$)$_4$ compounds inves-
tigated in this study that experience a structural transition to-
ward a symmetry lower than R32. This can be clearly seen in
the panels (b)–(d) of Fig. 3, which depict $l$ scans around
(0,0,1) for the Y, Gd, and Nd pendants of TbFe$_3$(BO$_3$)$_4$. In-
deed, pronounced peaks centered around (0,0,1) are observed
for both the Y- and Gd-based compounds but not for
NdFe$_3$(BO$_3$)$_4$.

Our observation clearly implies that materials undergo a
symmetry reduction at $T_S$ which results in a low-temperature
phase that is inconsistent with the P3121 space group as-
signed so far. The reflections at (0,0,3/1 ± 1) have not been
reported earlier, which is probably due to the fact that their
intensities are about four orders of magnitude weaker than
that at (0,0,3) and thus can easily be overlooked unless the
experiment relies on single crystals and x rays from high
brilliance sources like synchrotron radiation which probe the
crystal’s bulk.

![Fig. 3](image1.png)

**Fig. 3.** (Color online) (a) Scan at $T = 2$ K along the (0,0,l) direction for TbFe$_3$(BO$_3$)$_4$ showing the new superlattice re-
fections at (0,0,3/1 ± 1). For clarity the (0,0,3) peak is not shown since it does not fit onto the scale. Insets in (a) show that these reflections are absent in the high-temperature phase R32. The high-temperature data are shifted by $10^4$ counts for clarity. (b) and (c) present $l$ scans showing the (0,0,1) reflection at tempera-
tures below $T_S$ for YFe$_3$(BO$_3$)$_4$ and GdFe$_3$(BO$_3$)$_4$, respectively. (d) In contrast NdFe$_3$(BO$_3$)$_4$ exhibits only the
(0,0,3) reflection at all temperatures.

![Fig. 4](image2.png)

**Fig. 4.** (Color online) Structural and thermodynamic properties of TbFe$_3$(BO$_3$)$_4$. (a) shows the hard x-ray-integrated intensities of the reflections (0,0,1), (0,0,2), and (0,0,3), (b) heat capacity. Plot (c) shows the zero-field-cooled (ZFC) magnetic susceptibility when the field is applied parallel to $a$ and $c$, respectively, vs temperature. Vertical lines denote the structural and magnetic phase transitions.
No possible symmetry subgroup of the R32 space group yields conditions that satisfy the presence of the (0,0,1) and (0,0,2) reflections. There are only two possible reasons that could explain them. The first possibility is related to the spiral chains of octahedra which run along the c axis and yield the threefold screw axis ($3_1$) symmetry feature. The presence of the (0,0,1) reflection can be interpreted as a superlattice reflection resulting from a slight deviation of the Fe-atom positions from the symmetry positions generated by the screw axis, e.g., by a slight displacement in the vertical direction from the symmetry position, resulting in a modulation that requires a tripling of the unit cell in order to fully describe the symmetry of the structure. The second possible explanation is based on a special case of multiple diffraction. More precisely, the symmetry reduction to $P3_1$ could, in principle, allow multiple scattering by planes in other orientations within the crystal with a condition that is not possible at the higher R32 symmetry. In general, multiple scattering requires special geometry conditions which are already violated at small changes in the azimuth angle. In order to discard multiple scattering events, azimuth scans on the (0,0,1) reflection were performed with the result that the reflection remains observable even at azimuth angles larger than 90°. Since multiple scattering is rapidly suppressed by rotating the crystal along the azimuth direction, multiple scattering can be disregarded as the origin of (0,0,3l±1) reflections. Our data thus imply that the superlattice reflections come from small structural distortions, as previously discussed, and not from multiple scattering events.

Coming back to NdFe$_3$(BO$_3$)$_4$, this compound shows the largest magnetic induced electric polarization measured among the ferroborates. Since in this compound no structural transition is present, i.e., no (0,0,3l±1) reflections are observed [cf. Fig. 3(d)]. Thus, we can easily rule out the distortions responsible for these reflections as the origin of the electric polarization present in some of these compounds.

B. Superlattice reflections in the antiferromagnetic phase

Upon close inspection of the (0,0,l) scans in the antiferromagnetically ordered phase ($T<T_N$) we observe further weak superlattice reflections at (0,0,1.5) with an intensity about six to seven orders of magnitude smaller than the main (0,0,3) reflection. A representative example for this reflection is shown in Fig. 5(a) for the case of GdFe$_3$(BO$_3$)$_4$. Judging from the Miller indices of this reflection, the ordering of the magnetic ions generates an additional symmetry (superlattice) which is commensurate with the chemical structure and involves a doubling of the unit cell along the c direction. As can be seen in the data for GdFe$_3$(BO$_3$)$_4$, the peak gradually emerges from the background a few degrees below $T_N=36.6$ K and persists below 30 K with constant intensity down to 10 K. Upon cooling further the peak abruptly vanishes and remains absent at $T\approx 9$ K. Figure 6 shows the temperature dependence of the peak intensity in comparison with the specific heat. Obviously, the disappearance of the peak occurs exactly at the spin-reorientation transition at $T_{SR}=9.3$ K where the Fe spins turn from an easy-plane configuration in $ab$ to an easy-axis one along the c axis. This suggests that the superstructure which gives rise to the different superlattice reflections is related to the in-plane orientation of the iron spins.

This conjecture is corroborated by further investigations on the Y-, Nd-, and Tb-based compounds which exhibit in-plane Fe spin order (Y, Nd) and c-axis-oriented moments (Tb), respectively. Figure 7 shows the temperature dependence of the specific heat, magnetic susceptibility, and diffraction peak intensities for YFe$_3$(BO$_3$)$_4$. The onset of antiferromagnetic order of the iron spin with $ab$ orientation below $T_N=37$ K can clearly be inferred from the strong peak in the specific heat at this temperature and the strong decrease in the in-plane magnetic susceptibilities. Similarly as in GdFe$_3$(BO$_3$)$_4$, the (0,0,1.5) peak emerges below $T_N$. We point out, however, that the peak could be resolved only below 20 K.

**FIG. 5.** (Color online) l scans on GdFe$_3$(BO$_3$)$_4$ showing the magnetic (0,0,1.5) reflection at (a) $B=0$ and (b) $B=0.6$ T, as a function of temperature.

**FIG. 6.** (Color online) (a) Heat capacity and (b) hard x-ray-integrated intensities measured on GdFe$_3$(BO$_3$)$_4$. The superlattice peak (0,0,1.5) is present only in the temperature region $T_{SR}<T<T_N$, where the iron spins are aligned in the $ab$ plane. The inset in figure (a) shows the anomaly at the structural phase transition at $T_S=155$ K.
We find a very similar result for NdFe$_3$BO$_3$ as is shown in Fig. 8. The magnetic-ordering temperature $T_N$ is somewhat reduced in this material as compared to the previous discussed cases. As in YFe$_3$BO$_3$, the spin configuration is in plane as is signaled by the magnetic susceptibility shown in Fig. 8 and a superlattice reflection at $0.0,0.15$ is observed throughout the antiferromagnetic phase cf. Fig. 8. Note that in contrast to the other compounds the crystal symmetry remains $R32$ down to lowest temperature.

In contrast to these previous cases, in TbFe$_3$BO$_3$ the Fe moments are parallel to the $c$ axis and no superlattice reflection is present in the whole zero magnetic field phase at $T_N=39$ K. Thus, the aforediscussed conjecture of in-plane-oriented Fe moments as the required condition for observing the superlattice peaks is further substantiated.

C. Field dependence of the (0,0,1.5) reflection

In order to manipulate the Fe spin orientation and thereby investigate the field dependence of the (0,0,1.5) reflection we applied external magnetic fields. In TbFe$_3$(BO)$_3$, which exhibits AFM order with $c$ as the easy axis in zero field, the metamagnetic transition which occurs upon the application of an external magnetic field parallel $c$ induces an in-plane configuration of the iron spins. Figure 9(b) reproduces the magnetic phase diagram of this compound from Ref. 3 which allows to elucidate the temperature and magnetic field dependence of the metamagnetic transition. Figure 9(a) shows that at low temperature $T=2$ K the (0,0,1.5) peak emerges from the background at magnetic fields $B=3.5$ T, i.e., as soon as the Fe moments are oriented in plane, it quickly gains intensity up to saturation at higher magnetic fields [see

FIG. 7. (Color online) (a) Heat capacity, (b) ZFC static magnetic susceptibility, and (c) hard x-ray-integrated intensities measured on YFe$_3$(BO)$_3$. (0,0,1) and (0,0,2) reflections are present below $T_N$ and the superlattice reflection (0,0,1.5) appears when the magnetic order of the samples evolves.

FIG. 8. (Color online) Low-temperature behavior of NdFe$_3$(BO)$_3$. (a) Heat capacity, (b) ZFC magnetic susceptibility, and (c) hard x-ray-integrated intensities. The dashed line indicates the ordering temperature and shows the correlation between magnetic ordering of the sample and the appearance of the superlattice peak (0,0,1.5).

FIG. 9. (Color online) Hard x-rays diffraction measurements on TbFe$_3$(BO)$_3$. Plot (a) shows the evolution of the (0,0,1.5) reflection as the applied magnetic field is increased from 0 to 8 T. Dashed lines refer to the FWHM of the (0,0,3) reflection, which was used as the experimental resolution function in order to estimate the correlation length of the magnetic signal (read text). (b) shows the phase diagram reproduced from Ref. 3.
NONRESONANT X-RAY MAGNETIC SCATTERING ON...

FIG. 10. (Color online) Hard x-rays diffraction integrated intensities as a function of magnetic field for the reflections (0,0,1), (0,0,1.5), (0,0,2), and (0,0,3) measured on (a) NdFe$_4$(BO$_3$)$_4$ and (b) TbFe$_4$(BO$_3$)$_4$. The insets show the evolution of the magnetic (0,0,1.5) peak at a given applied magnetic field, as a function of temperature.

The peak width does not change when increasing the field, supporting the picture of a spin flop where there is no significant change in the spin-correlation length, but only of the spin direction. The inset in Fig. 10(b) shows the intensity of this peak as a function of temperature at a fixed external field of $B=5$ T parallel to the basal plane, which corresponds to a horizontal cut through the phase diagram in Fig. 9. As can be seen in the figure, the peak intensity is constant at $T\approx 15$ K, rapidly decreases at higher $T$ and eventually vanishes at $T\approx 20$ K. Note, that upon crossing this temperature the Fe-moments reorient from the in plane to the parallel c configuration of the AFM phase. We have performed a similar measurement also for GdFe$_4$(BO$_3$)$_4$. As has been discussed already above, in zero magnetic field, the (0,0,1.5) reflection appears only in the temperature range between $T_{SR}$ and $T_N$ [Fig. 6(b)]. According to Yen et al. the spin-reorientation temperature $T_{SR}$ decreases if a magnetic field parallel to the c axis is applied. As can be seen in Fig. 6(b) for the case of $B=0.6$ T, the downshift of $T_{SR}$ also leads to a shift of the lowest temperature at which the (0,0,1.5) reflection appears. To be specific, at the applied magnetic field the reflection is well resolved at $T\approx 7$ K, i.e., in perfect agreement with the phase diagram reported by Yen et al.

Both examples where the (0,0,1.5) superlattice reflection is induced by an external magnetic field unambiguously demonstrate that there is a clear one-to-one correlation between this reflection and the in-plane orientation of the Fe spins. In the following we point out that even more subtle changes in the magnetic structure have an impact on the intensity of the reflection. Figure 10(a) shows the integrated intensity of the magnetic reflection as a function of magnetic field for NdFe$_4$(BO$_3$)$_4$ with the magnetic field oriented in plane. It can be seen that the magnetic peak intensity increases with increasing the field, until it reaches saturation at $B\approx 1$ T. Results of a detailed measurement in this field range are shown in Fig. 11(a) and reveal that the peak intensity exhibits a steep increase at $0.5\leq B\leq 1.2$ T while it is constant at lower and higher fields. Interestingly this increase in peak intensity coincides with an increase in magnetization as is shown in Fig. 11(b). The small jump in magnetization is the signature of a spin flop of both Fe and Nd moments, along a direction perpendicular to the external field within the basal plane.

D. Discussion

The magnetic structure of RFe$_4$(BO$_3$)$_4$ ($R=\text{Y, Nd, and Tb}$) has been studied in a number of different neutron-diffraction experiments. Depending on the compound, either a spin spiral [NdFe$_4$(BO$_3$)$_4$] propagating along the c axis or a Néel state has been inferred from the data. In all cases commensurate magnetic superlattice reflections occur at (0,0,1,5), i.e., the magnetic supercell is doubled along the c axis. Hence, at first glance two possible origins of the x-ray superlattice reflections should be considered. First, the observed superlattice reflections could be of magnetic nature and thus represent the x-ray pendant of the magnetic reflections seen in neutron scattering. Second, the superlattice reflections could result from a weak structural distortion that is imposed by the magnetic ordering. An appealing scenario for the latter which reasonably explains the observed correlation between the occurrence of the superlattice reflections and the orientation of...
the Fe spins is a magnetic spiral state which propagates along the $c$ axis [as is concluded from neutron data for NdFe$_3$(BO$_3$)$_4$ (Ref. 18)] and thus could, in principle, lead to a structural distortion following the spin spiral. This spiral state (including the assumed lattice distortion) requires the Fe moments or a component of them to lie in the $ab$ plane and thus it has to vanish as soon as the Fe moments are fully oriented along $c$.

On the other hand, there are compelling reasons to rationalize the $(0,0,1.5)$ superlattice reflection in terms of purely magnetic scattering. The Bragg angle for this reflection at $h\nu=100$ keV is $\theta_{(0,0,1.5)}=0.705^\circ$, i.e., close to $\theta \rightarrow 0$. As discussed in Sec. II, the cross section for magnetic scattering under this experimental conditions allows to observe magnetic scattering when the spins of the unpaired electrons have a component perpendicular to the scattering plane [Eq. (3)]. In our experimental setup this is indeed the case if the iron spins lie in the $ab$ plane of the sample. Thus, the surprising dependence of the peak intensity on the spin orientation is naturally explained without further assumptions. Moreover, the intensity of this reflection is around seven orders of magnitude weaker than the $(0,0,3)$ Bragg peak, which is just the expected order of magnitude for magnetic reflections [cf. Eq. (1)]. Thus it seems more reasonable to assign a magnetic origin to the superlattice reflection.

1. $q$ and azimuth dependence of the magnetic reflection

In order to verify the latter conclusion we have performed measurements of the $q$ dependence of the intensity of both the structural $(0,0,3)$ Bragg reflections and of the $(0,0,3/\pm 1.5)$ reflections, where we studied GdFe$_3$(BO$_3$)$_4$ as a representative case (see Fig. 12). As a function of $q$, the measured intensity of the structural Bragg reflections (filled triangles) evolves as it is expected from structure factor calculations (open triangles). One can see that even at large $q$ values the charge reflections are still strong. A much faster decrease in intensity with increasing $q$ is expected for magnetic reflections as is shown in the figure by the open circles, which agrees well with the observed intensities of the $(0,0,3/\pm 1.5)$ reflections and thus allows to unambiguously identify the peak as magnetic.\(^{37}\)

In principle, the peak intensity at $(0,0,1.5)$ should depend on the azimuth angle if an easy axis exists when the Fe spins lie within the $ab$ plane. Measurements at different azimuth angles at $q=(0,0,1.5)$ are presented in Fig. 13. Since the integrated intensity of the magnetic peak shows a constant azimuth dependence, only two possible scenarios are in agreement with the experiment. The first possible interpretation involves an equally populated domain structure, where the three equivalent domains in the basal plane are rotated 120° relative to each other. Figure 13 shows the expected signal for the three different domains and the horizontal red line (Sum) refers to the summation of the three domain signals. The second possible reason of such azimuth dependence is the formation of a spin spiral as suggested from neutron-diffraction data.\(^{18}\)

It is interesting to point out in this regard the aforementioned effect of an external magnetic field on the $(0,0,1.5)$ reflection where the field was applied in plane. Since in our setup the field direction lies in the scattering plane, a spin flop of the iron moments will definitely manipulate the number of spins perpendicular to the scattering plane. More specifically in NdFe$_3$(BO$_3$)$_4$, following a spin model suggested by Volkov et al.,\(^{36}\) one should expect three equivalent easy directions of magnetization in the basal plane [see inset in Fig. 11(a)]. The applied magnetic field causes the spins to flop into a direction perpendicular to the applied field, i.e., perpendicular to the x-ray scattering plane. From Eq. (3) it is clear that an increase in the spin component perpendicular to the scattering plane enlarges the magnetic scattering cross section and therefore yields an increase in the intensity. Figure 11(a) actually shows the enhancement of the magnetic intensity due to the rotation of the magnetic moments along the scattering plane normal.

2. Correlation length \( \xi \) of the magnetic domains

The width of the magnetic reflection is around twice the width of the nearest Bragg reflection, as shown by the dashed lines in Fig. 9(a) for TbFe\(_3\)(BO\(_3\))\(_4\). This suggests that the correlation length, or size of the magnetic domains within the crystal, has a finite size. Experimentally, the measured diffracted signal is a convolution of the experimental resolution function and the intrinsic diffracted signal from the crystal. Hence, the measured signal \( h \) can be expressed as

\[
[f * g](\tau) = h(\tau), \tag{5}
\]

where \([f * g]\) denotes the convolution of the experimental resolution function \( f \) and the intrinsic signal \( g \). If we consider the Gaussian fit profile of the \((0,0,3)\) Bragg reflection as our experimental resolution function where FWHM\(_{(0,0,3)}=0.0072(1) \) r.l.u., an estimation of the intrinsic magnetic diffracted signal can be obtained by a deconvolution from the measured signal. As the measured signal can also be expressed by a Gaussian, thus the intrinsic function \( g \) is also a Gaussian with full width at half maximum (FWHM) equal to

\[
\Delta g = \sqrt{\Delta h^2 - \Delta f^2}. \tag{6}
\]

After deconvolution, the correlation length of the magnetic domains along the \( c \) direction was estimated assuming a perfect crystal with no strain, assumption supported by the small crystal mosaicity, 0.0060(1)°, determined from the 2\( \theta \) scan of the \((0,0,3)\) Bragg reflection. For all compounds we find \( \xi_c \approx 100 \) Å (cf. Table I for details). The correlation length \( \xi_c \) was calculated using the following relation:

\[
\frac{1}{\xi_c} = 2\pi \left( \frac{0.094411}{0.094411} \right) \tag{7}
\]

3. Magnetic structure factor and the spin moment \( S \) in GdFe\(_3\)(BO\(_3\))\(_4\)

Finally, according to Eq. (4) it is possible to determine the size of the component of \( S \) perpendicular to the scattering plane from the measured integrated intensity of a magnetic reflection. In the kinematical approximation, the magnetic and charge reflectivity ratio of a crystal in a Laue symmetry has the following form:

\[
\frac{R_m}{R_c} = \frac{I_m}{I_c} = \frac{\lambda^2}{d^2} \sin^2 \theta_B \left( \frac{|F_m|}{|F_c|} \right)^2 k, \tag{8}
\]

where \( I_m, I_c, |F_m| \times S_2 \) and \( |F_c| \) are the measured integrated intensities of the magnetic and charge reflections and the magnetic and charge structure factors, respectively. \( \theta_B \) is the Bragg angle of the magnetic and charge scattering, \( d \) is the interatomic spacing of the magnetic reflections and \( k=3 \) is a correction factor that compensates for the three equally populated domains in which the magnetic moment lies in the hexagonal basal plane. The direct measurement of the intensity of the \((0,0,3)\) Bragg peak is not possible since the strong intensity saturates the detector. It is necessary to measure this peak at different radiation absorbers and finally extrapolate to absorber 0. Using the calculated value of \(|F_m|\) and knowing that only the iron atoms contribute to the magnetic scattering in the sample, the solution of Eq. (8) for \(|F_m|\) yields an estimated value of \( S_2=1.49+0.09 \). Since this values is a projection of \( S \) along the scattering plane normal, which coincides with the \( ab \) plane as discussed before, one can calculate the angle between the iron moments and the basal plane. Taking \( S=5/2 \) as reported from magnetization measurements,\(^8\) this angle is \( 53° \pm 3° \), which is in close agreement with the angle found by resonant scattering experiments\(^{27} \) which is around \( 45° \). Deviation from this values could arise from experimental restrictions, since the determination of the primary intensity of the \((0,0,3)\) reflection is indirect and also that the weakness of the magnetic intensity can bring some systematic error while data acquisition.

V. SUMMARY

Structural and magnetic properties on compounds of the form RFe\(_3\)(BO\(_3\))\(_4\) (R=Gd, Tb, Nd, and Y) have been studied by means of high-energy x-ray diffraction. Due to the high-energy photons used during the experiment, NRXMS could be observed on all the compounds at temperatures below the magnetic-order temperature when the AFM vector lies in the \( ab \) plane. The study of the magnetic reflection as a function of temperature and applied magnetic field shows the different metamagnetic transitions such as spin flocks and spin-reorientation transitions in TbFe\(_3\)(BO\(_3\))\(_4\), NdFe\(_3\)(BO\(_3\))\(_4\), and GdFe\(_3\)(BO\(_3\))\(_4\). Moreover NRXMS allowed us to corroborate the magnetic structures obtained from neutron-scattering experiments. Detailed analysis of the magnetically diffracted intensities as a function of magnetic field and azimuth angle in NdFe\(_3\)(BO\(_3\))\(_4\) and GdFe\(_3\)(BO\(_3\))\(_4\), respectively, suggests that the magnetic moments of the Fe ions are aligned in the crystallographic \( a \) axis, leading to a domain structure formation since there are three equivalent directions in the hexagonal basal plane. For GdFe\(_3\)(BO\(_3\))\(_4\) we extracted an out-of-plane angle of \( 53° \pm 3° \) for the iron moments and for all the compounds, a correlation length of the magnetic domains of \( \approx 100 \) Å was estimated.

Furthermore, we observed the presence of different superlattice reflections at \((0,0,3/\pm 1)\). These suggest that the symmetry of the crystal has not been properly assigned, as these reflections violate the reflection conditions for the until now accepted \( P3_121 \) space group.
