Abstract

The MAGIC stereoscopic system collected 69 hours of Crab Nebula data between October 2009 and April 2011. Analysis of this data sample using the latest improvements in the MAGIC stereoscopic software provided an unprecedented precision of spectral and night-by-night light curve determination at gamma rays. We derived a differential spectrum with a single instrument from 50 GeV up to almost 30 TeV with 5 bins per energy decade. In the low energies, MAGIC results, combined with the *Fermi*-LAT data, show a flat Inverse Compton peak. The *Fermi*-LAT and MAGIC spectral data were fit from 1 GeV to 30 TeV with a log-parabola, yielding a peak position at (53 ± 3) GeV with a $\chi^2_{\rm red} = 82/27$ (error probably underestimated due to the bad fit quality), showing that the log-parabola is not a good representation of the Inverse Compton peak of the Crab Nebula. There is no hint of the integral flux variability on daily scales at energies above 300 GeV if accounting for systematic uncertainties of the measurement. We consider two state-of-the-art theoretical models to describe the overall spectral energy distribution of the Crab Nebula. The constant B-field model cannot satisfactorily reproduce the VHE spectral measurements presented in this work, mostly troubled by the broadness of the observed IC peak. Most probably this implies that the assumption of the homogeneity of the magnetic field inside the nebula is incorrect. On the other hand, the time-dependent 1D spectral model provides a good fit of the new VHE results when considering a $80 \, \mu$G magnetic field. However, it fails to match the data when including the morphology of the nebula at lower wavelengths.

Keywords: Crab Nebula, Pulsar Wind Nebulae, MAGIC telescopes, Imaging Atmospheric Cherenkov Telescopes, very high energy gamma rays

1. Introduction

The pulsar wind nebula (PWN) of the Crab pulsar is located in the center of the remnant from the supernova of 1054 A.D. (Stephenson & Green 2003). It continuously supplies relativistic particles, mainly positrons and electrons, that advect in the magnetized wind of the neutron star. This pulsar wind terminates in a standing shock where particles are thought to be accelerated up to ultra-relativistic energies, and their pitch angles are randomized. The outflow interacts with the surrounding magnetic and photon fields creating the PWN. The nebula emits synchrotron radiation which is observed from radio frequencies up to soft γ-rays. This emission is well described by the magnetohydrodynamic model (MHD, Kennel & Coroniti 1984). At higher energies (above 1 GeV), the overall emission is dominated by the Inverse Compton (IC) scattering of synchrotron photons of the nebula by the relativistic electrons (de Jager & Harding 1992; Atoyan & Aharonian 1996).

The Crab Nebula is one of the best studied objects in the sky. Due to its brightness at all wavelengths, precise measurements can be provided by different kinds of instruments, allowing for a detailed examination of its physics. The IC emission from the Crab Nebula was detected for the first time above 700 GeV by the pioneering Whipple imaging atmospheric Cherenkov telescope in 1989 (Weekes et al. 1989). Since then, the imaging Cherenkov technique was successfully used to extend the Crab Nebula differential energy spectrum from few hundred GeV up to 80 TeV (Aharonian et al. 2004, 2006, HEGRA and H.E.S.S., respectively). However, the spectrum below 200 GeV has been observed only recently, revealing the long-anticipated IC peak in the distribution. On the one hand, ground-based imaging atmospheric Cherenkov telescopes (IACTs) with larger reflective surface reached lower energy thresholds, below 100 GeV. Thanks to the observations using the stand-alone first MAGIC[1] telescope (MAGIC-I) a hardening of the spectrum below a few hundred GeV was found (Albert et al. 2008a). On the other hand, at even lower energies, measurements by *Fermi*-LAT filled the gap between few and hundred GeV (Abdo et al. 2010). The spectral overlap between the MAGIC-I and the *Fermi*-LAT measurements was, however, not very good leaving open the ques-

---

[1]Major Air Gamma-Ray Cherenkov

tion of the precise energy of the IC peak. Moreover, the quality of the available data around the IC peak was insufficient to rule out existing PWN models or at least distinguish among them. The goal of this work was to measure the Crab Nebula differential energy spectrum with a higher statistical precision and down to 50 GeV by using the stereoscopic system of the two MAGIC telescopes and compare it with the state-of-the art PWN models.

Because of its apparent overall flux steadiness, the Crab Nebula was adopted as standard candle at many energy regimes. It has been used to cross-calibrate X-ray and γ-ray telescopes, to check the instrument performance over time, and to provide units for the emission of other astrophysical objects. However, in 2010 September, both *AGILE* and *Fermi*-LAT detected an enhancement of the γ-ray flux above 100 MeV (Tavani et al. 2011; Abdo et al. 2011). Variability has also been measured in X rays on yearly time scale (Wilson-Hodge et al. 2011). A search for possible flux variations in MAGIC data coinciding with the GeV flares will be discussed in a separate paper.

2. Observations and analysis

MAGIC currently consists of two 17 m diameter IACTs located in the Canary Island of La Palma (Spain) at a height of 2200 m above sea level. It looks at the very-high-energy (VHE) sky in the energy range between few tens of GeV and few tens of TeV. MAGIC started operations in autumn 2004 as a single telescope, MAGIC-I, and became a stereoscopic system five years later in 2009. During the summers 2011 and 2012, MAGIC underwent a major upgrade involving the readout systems of both telescopes and the MAGIC-I camera (Mazin et al. 2013). The stereoscopic observation mode led to a significant improvement in the performance of the instrument with an increase in sensitivity by a factor of more than two, while the upgrade, meant to equalize the performance of the two telescopes, improved the sensitivity of the instrument mainly at energies below 200 GeV (Sitarek et al. 2013).

In this work we use MAGIC stereoscopic observations of the Crab Nebula carried out between October 2009 and April 2011, before the above-mentioned upgrade[2]. During this period the performance of the instrument is described in detail in Aleksić et al. (2012), with an integral sensitivity above 300 GeV of 9×10^{-13} cm^{-2} s^{-1}, which is the flux that can be reached with 5-σ in 50 h of observations at low zenith angles for sources with a power law spectrum with a photon index of 2.6. The selected data set includes observations performed in wobble mode (Fomin et al. 1994) at zenith angles between 5° and 62°. Data affected by hardware problems, bad atmospheric conditions, or displaying unusual background rates are rejected in order to ensure a stable performance, resulting in 69 h of effective time.

The analysis is performed by using the tools of the standard MAGIC analysis software (Zanin et al. 2013). Each telescope records only the events selected by the hardware stereo trigger. For every event the image cleaning procedure selects the pixels which have significant signal and removes the rest. The obtained reconstructed image is then quantified with a few simple parameters. For the analysis of the Crab Nebula data set we used *sum image cleaning*, a new algorithm which lowers the analysis energy threshold to 55 GeV and provides a 15% improvement in sensitivity below 150 GeV (Lombardi 2011).

After the image cleaning procedure, stereoscopic pairs of images are combined and the shower direction is determined as the crossing point of the corresponding single-telescope directions. The reconstruction of the shower direction is later improved by applying an upgraded version of the *disp* method (Zanin et al. 2013). The background rejection relies on the definition of the multi-variable parameter *hadronness*, which is computed by means of a Random Forest (RF) algorithm (Albert et al. 2008b). RF uses as input a small set of image parameters from both telescopes, together with the information about the height of the shower maximum in the atmosphere provided by the stereoscopic reconstruction. The γ-ray signal is estimated through the distribution of the squared angular distance (θ^2) between the reconstructed and the catalog source position. The energy of each event is estimated by using look-up tables created from

---

[2]Data after the upgrade are currently being studied and will be matter of a forthcoming publication.

$$\frac{dN}{dEdAdt} = (3.23 \pm 0.03) \cdot 10^{-11} \left(\frac{E}{TeV}\right)^{(-2.47\pm0.01)+(-0.24\pm0.01)\log\left(\frac{E}{TeV}\right)} (TeV^{-1}.cm^{-2}.s^{-1})$$
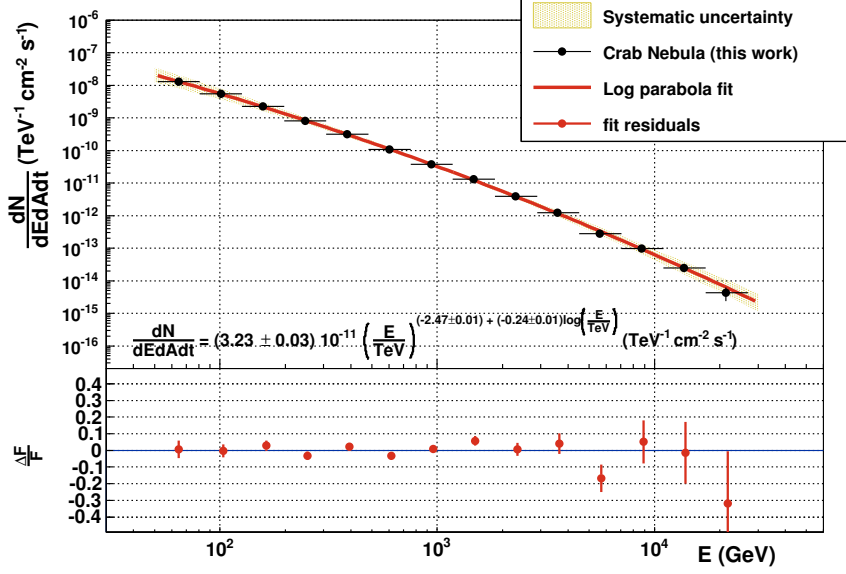

Figure 1: Differential energy spectrum of the Crab Nebula obtained with data recorded by the MAGIC stereoscopic system.

Monte Carlo (MC) simulated γ-ray events. For the computation of the differential energy spectrum, the γ-ray signal in each energy bin is determined by selecting a soft *hadronness* cut, which retains 90% of the γ-ray events ensuring a good agreement between data and MC. Next, an unfolding procedure is applied to the obtained differential energy spectra to correct for the energy bias and the finite energy resolution of the detector. In particular, we apply five different unfolding methods described in Albert et al. (2007) and check the consistency of the results. For the light curves, we compute integral γ-ray fluxes in a given energy range as a function of time. No full-fledged unfolding procedure is used here. Instead, a correction is applied to the effective area in the selected energy range to account for the spillover of the Monte Carlo simulated events with (true) energy outside of it, under the assumption of a given shape of the differential energy spectrum.

Since our data set spans a large zenith angle range (5° to 62°), we divide the data sample in three zenith angle ranges[3] to better account for corresponding variations in the image parameters: a) 5° to 35°, b) 35° to 50°, and c) 50° to 62°. The matrices for the background rejection obtained through the RF, as well as the look-up tables for the energy estimation, are computed

separately for each sub-sample. The three independent analyses are then combined with the spectral unfolding procedure as described above.

3. Results

3.1. The differential energy spectrum

The main result of this work, shown in Figure 1, consists of an unprecedented differential energy spectrum of the Crab Nebula which covers almost three decades in energy, from 50 GeV up to 30 TeV, and spans eight orders of magnitude in flux. It is unfolded with Bertero's method (Bertero 1989), but all the other considered unfolding methods provide compatible results within the statistical errors. This is a high-precision measurement with five spectral points per energy decade and statistical errors as low as 5% below 150 GeV. Up to 10 TeV, the overall uncertainty is dominated by systematic uncertainties rather than statistical ones. The systematic uncertainties, displayed in Figure 1 as a shadowed area, will be discussed in detail below.

The resulting differential energy spectrum cannot be fitted by a simple power law over the whole energy range measured by MAGIC. For the analytical description of the measured spectrum we consider two different functions, which were previ-

---

[3]The binning in zenith angle (zd) is equidistant in cos(zd).

4

ously used in literature for the Crab Nebula at VHE gamma rays:

- a power law with exponential cut off (Aharonian et al. 2006):

$$dN/dE = f_0 \left(\frac{E}{E_0}\right)^{-\alpha} \exp\left(-\frac{E}{E_c}\right)$$

- a log-parabola (Albert et al. 2008a):

$$dN/dE = f_0 \left(\frac{E}{E_0}\right)^{-\alpha+\beta \log(E/E_0)}$$

The fits do not include systematic uncertainties, but they take into account the correlations between the spectral energy points. The power law with exponential cut off (not shown in the figure) results in a flux normalization $f_0 = (4.19 \pm 0.03)\,10^{-11}$ TeV^{-1} cm^{-2} s^{-1}, a photon index $\alpha = 2.15 \pm 0.01$, and a cut off at $E_c = (4.3 \pm 0.5)$ TeV with a $\chi^2_{\rm red}$ of 88/11. The low fit probability is mainly due to the disagreement between the sharp cut off predicted by the fit function and the MAGIC data. The fit to the log-parabola gives a flux normalization $f_0 = (3.23 \pm 0.03)$ 10^{-11} TeV^{-1} cm^{-2} s^{-1}, a photon index $\alpha = 2.47 \pm 0.01$, and a curvature parameter $\beta = -0.24 \pm 0.01$. It has a $\chi^2_{\rm red}$ of 20/11. The parameter $E_0 = 1$ TeV for the two fits. The log-parabola provides a better fit compared to the power law with exponential cut off. In the bottom panel of Figure 1, one can see residuals between our measurements and the best fit. The fit results for the power law with exponential cut off and log-parabola are summarized in Table 1.

Parameter	Power law with cutoff	Log-parabola
f_0 (TeV^{-1} cm^{-2} s^{-1})	$(4.19 \pm 0.03)\,10^{-11}$	$(3.23 \pm 0.03)\,10^{-11}$
index α	2.15 ± 0.01	2.47 ± 0.01
curvature β	—	-0.24 ± 0.01
cutoff E_c (TeV)	4.3 ± 0.5	—
$\chi^2_{\rm red}$	87.8/11	20.3/11

Table 1: Best-fit parameters to the differential photon spectrum of the Crab Nebula obtained with MAGIC in the energy range between 50 GeV and 30 TeV.

The overall systematic uncertainty affecting the measurement of the differential energy spectrum of the Crab Nebula includes three different classes of effects: one on the energy scale,

the second in the flux normalization and the third on the spectral shape. The uncertainty on the energy scale is about 15–17%, whereas that for the flux normalization is about 11%, according to the specific studies in Aleksić et al. (2012). The estimation of the systematic error on the spectral shape is unique to this work since we further split the error into an uncertainty on the photon index and one on the curvature parameter, given the assumed log-parabola spectral shape. Both include a common uncertainty of 0.04 due to the non-linearity of the analog signal chain (Aleksić et al. 2012) as well as an individual uncertainty due to the analysis methods. The latter is evaluated as the RMS of the distributions of the α and the β parameters derived from different analyses performed with various RFs, different image cleaning algorithms, observation zenith angles, and efficiency of γ-ray selection cuts. This yields a systematic uncertainty on α of 0.03 and on β of 0.05. The overall systematic uncertainty for both α and β is calculated by summing up in quadratures these values to the above-mentioned uncertainty of 0.04 for the effect of the non-linearity, obtaining an overall of 0.05 and 0.07 for α and β, respectively.

3.2. Spectral energy distribution of the Crab Nebula

Figure 2 shows the spectral energy distribution (SED) for the MAGIC data (same data set as used for Figure 1), and compares it to the measurements by other IACTs (green, black and brown lines) as well as to the *Fermi*-LAT results for the Crab Nebula (magenta squares). In this work we consider the latest *Fermi*-LAT published results on the Crab Nebula, which include 33 months of data (Buehler et al. 2012). At low energies (50–200 GeV), MAGIC data overlaps with the *Fermi*-LAT measurements, showing an agreement, within the statistical errors, between the spectral points of the two experiments. The absolute calibration of the two different detection techniques is about 10% on the flux level or on the energy scale. At higher energies (above 10 TeV), a disagreement between HEGRA (Aharonian et al. 2004) and H.E.S.S. (Aharonian et al. 2006) measurements has been noted (green dash-triple-dotted and black dash-dotted lines, respectively). This may be due to
Figure 2: Spectral energy distribution of the Crab Nebula obtained with the MAGIC telescopes, together with the results from other γ-ray experiments. The black arrow indicates the systematic uncertainty on the energy scale. The solid red line is the log-parabola fit to the MAGIC data alone, whereas the blue dashed line is a combined fit to the *Fermi*-LAT and MAGIC data without assuming any systematic shift in energy between the two experiments (see text for details).

systematic uncertainties between the two experiments or may indicate a real spectral variability of the nebula. The relatively large systematic uncertainty of the MAGIC measurement and the lack of MAGIC data above 30 TeV do not favor either hypothesis. As at the highest energies of the MAGIC spectrum the statistical errors still dominate over the systematic ones, we may improve the result in future after taking a significant amount of additional Crab Nebula data with MAGIC.

In order to be independent from theoretical modeling and under the assumption that the IC contribution of the Crab Nebula emission along the electromagnetic spectrum can be represented, in a first approximation, by a log-parabola, we can estimate the position of the IC peak. In all fits described below we take the correlations between MAGIC spectral points into account and consider statistical errors only unless stated otherwise. If we consider MAGIC data alone we obtain a value for the IC peak energy of (103 ± 8) GeV ($\chi^2_{\rm red} = 20/11$), consistent

with the earlier MAGIC measurement with the single telescope ((77 ± 47) GeV, Albert et al. 2008a). To achieve a larger lever arm we fit MAGIC and *Fermi*-LAT spectral data points together starting from 1 GeV, corresponding to the energy of the lowest spectral point of the *Fermi*-LAT spectrum where the IC contribution dominates over synchrotron emission. The best fit result ($\chi^2_{\rm red} = 82/27$) is shown as dashed line in Figure 2. It results in an IC peak position at (53 ± 3) GeV. As stated above, this value is derived using statistical errors only, i.e. neglecting a possible systematic shift in energy or/and flux between the two experiments. If we allow for a systematic shift in the energy scale of the MAGIC data with respect to the *Fermi*-LAT data[4], the best fit ($\chi^2_{\rm red} = 74/26$) results in an IC peak position at (69 ± 7) GeV, requiring a +11% shift in the energy scale of the MAGIC measurement. The goodness of the fit is bad in both cases, with

---

[4]We consider *Fermi*-LAT to be better calibrated since it was absolutely calibrated with test beams at CERN before launch (Atwood et al. 2009), whereas there is no test beam for the IACT technique
Figure 3: Daily light curve of the Crab Nebula for energies above 300 GeV. The black vertical lines show statistical error bars, the grey ones the quadratic sum of statistical errors and a 12% systematic point-by-point uncertainty. The dashed horizontal line is the best fit value to a constant flux. The grey areas indicate the Crab flares as reported by AGILE and *Fermi*-LAT.

and without an energy scale shift in the MAGIC spectrum. This implies that the log-parabola function is not a good representation of the IC peak measured by *Fermi*-LAT and MAGIC. The log-parabola has been used many times in the literature because it describes approximately the overall IC peak shape of the Crab Nebula (as well as many other objects); but the quality of the data presented here shows clearly that the log-parabola cannot be used to describe the IC peak over an energy range spanning four decades. Because of this mismatch between the log-parabola model and the data, the IC peak position determined with the log-parabola fit depends on the fit range. For instance, if the starting fit point moves from 1 GeV to 10 GeV, the IC peak position increases from 53 GeV to 93 GeV, and the curvature increases by about 20%.

3.3. The light curve

In this section we present the light curve above 300 GeV from the Crab Nebula. This is meant to check the flux stability on time scales of days. The results are presented in Figure 3, which shows the MAGIC daily fluxes between October 15, 2009 and April 6, 2011, where the error bars indicate statistical (shown in black) and systematic errors (the combined error is shown in grey). The average flux above 300 GeV $F_{>300\,\text{GeV}}$ is:

$$F_{>300\,\text{GeV}} = (1.20 \pm 0.08_{stat} \pm 0.17_{sys}) \times 10^{-10} \text{cm}^{-2}\text{s}^{-1}$$

The systematic error on the integral flux is estimated to be 14%, without a possible shift in the energy scale. The derived Crab Nebula flux is stable (fit by a constant has a probability of 15%) within statistical errors and a 12% systematic point-by-point uncertainty, added in quadrature, in agreement with the expected systematic uncertainty for run-by-run data obtained in Aleksić et al. (2012). Note that the systematic uncertainty in Aleksić et al. (2012) was computed using the same source, the Crab Nebula. Thus, we cannot completely exclude the intrinsic variability on a level smaller than 12%. This point-by-point systematic uncertainty is attributed mainly to the transmission of the atmosphere for the Cherenkov light, which can change on a daily basis or even faster due to variations in the weather conditions, and the mirror reflectivity, which can change due to the deposition of dust. The grey areas correspond to the Crab flares at energies above 100 MeV as reported by AGILE and *Fermi*-LAT. MAGIC observed the Crab Nebula simultaneously during the flare that occurred on MJD = 55458 − 55460[5] but no enhanced activity above 300 GeV was detected.

4. Discussion

There are two broad classes of PWN models: the MHD models reproducing the energy-dependent morphology (Kennel & Coron

---

[5]The MAGIC data are centered around MJD = 55459.2

1984; de Jager & Harding 1992; Atoyan & Aharonian 1996; de Jager et al. 1996) and time-dependent spherically symmetric one-dimensional (1D) PWN spectral models (Aharonian et al. 1997; Bednarek & Bartosik 2003, 2005).

The broad-band SED of the Crab Nebula has been tested against models in these two categories:

- a model based on the one first suggested by Hillas et al. (1998) assuming a static, constant magnetic field, B;

- a time-dependent spherically symmetric (1D) PWN spectral model presented in Martín et al. (2012).

4.1. Static, constant B-field model

The *constant B-field model* was introduced in Meyer et al. (2010) and follows the prescription put forward in Hillas et al. (1998) and Aharonian et al. (2004). The Crab Nebula is assumed to be homogeneously filled with a constant magnetic field and two distinct electron populations: relic electrons (responsible for the radio synchrotron emission) and wind electrons. The relic electron population is needed to explain the break in the synchrotron spectrum at optical wavelengths (see also Sec. 6 in Meyer et al. 2010). The relic electrons might be the result of a rapid spin-down phase in the early stages of the evolution of the Crab Nebula (Atoyan 1999). The populations can be regarded as averaged representations of the electron distributions. The two spectra were modeled with a simple power law and a broken power law with a super-exponential cut off for relic and wind electrons, respectively. For their definition we refer the reader to Meyer et al. (Eq. 1 and 2 in 2010). The minimal gamma factor of the relic electrons was fixed to 3.08 in the fit as it is not constrained by the observable part of the SED. Following Hillas et al. (1998), the spatial distributions of both the seed photons and pulsar wind electrons were described with Gaussian functions in distance to the nebula's center (see discussion and Eq. A.1 and A.2 in Meyer et al. 2010), whereas the relic electron population is uniformly distributed throughout the nebula. The variances of the Gaussian distributions vary with energy, thus accounting for the observed smaller size of

Table 2: Best-fit parameters with uncertainties for the constant B-field model. The definition of the model parameters is given in Meyer et al. (2010).

Magnitude	Crab Nebula
Magnetic field	
B (μG)	143.46 ±0.82
Dust component	
$\ln(N_\mathrm{dust})$	-29.87 ±0.08

$\ln N_w$	78.46 ±0.01
$\ln \gamma_w^\mathrm{min}$	12.90 ±0.14
$1/\ln \gamma_w^\mathrm{break}$	-19.48 ±0.00
$\ln \gamma_w^\mathrm{max}$	22.68 ±0.02
β	3.76 ±0.75

the nebula at shorter wavelengths. The thermal dust emission was assumed to follow a gray body spectrum. In contrast to Meyer et al. (2010), also the parameters describing such component were left free to vary, except for the extension of the thermal dust emission (θ_dust = 1.3′ following Hillas et al. 1998).

The electron spectra were calculated using the same synchrotron data as in Meyer et al. (2010) expect for the new *Fermi*-LAT data (Buehler et al. 2012). For a given magnetic field strength, the parameters of the electron spectra were derived from the fit to the synchrotron data between $4 \cdot 10^{-6}$ eV $\leqslant \nu \leqslant 0.4$ GeV, using a χ^2 minimization implemented with the `python` interface of `MINUIT` (James 1998). Subsequently, the magnetic field and the parameters describing the thermal dust emission were varied until the IC part of the SED (E > 0.4 GeV) presented in this
Figure 4: *On the left:* The overall spectral energy distribution of the Crab Nebula from radio to γ rays. Lines are best fit results based on the model of Meyer et al. (2010) (MHZ), see text for details. The thin lines show individual components of the photon spectrum (see the inlay), and the thick blue line identifies the overall emission. Historical data (brown) are from Meyer et al. (2010), *Fermi*-LAT data (pink) are from Buehler et al. (2012), and the VHE data are from this work. *On the right:* Zoom in the γ-ray regime.

work is reproduced best. The full Klein-Nishina cross section is used to calculate the IC emission when the following photon fields are considered: synchrotron and thermal dust emission, as well as the cosmic microwave background (CMB).

Allowing for a point-wise systematic uncertainty of 8% of the flux (added in quadrature, Meyer et al. 2010), the synchrotron emission is accurately reproduced with $\chi^2_{\rm red} = 249/217 = 1.15$ (Figure 4). Above 0.4 GeV, the data is poorly described and the fit only converges if an additional (unrealistically large) systematic uncertainty of 17% is assumed, resulting in $\chi^2_{\rm red} = 48.8/31 = 1.57$.

The final best-fit parameters are given in Table 2. The steepness of $\chi^2(B)$ distribution explains the small uncertainties of the best-fit parameters, especially for the magnetic field, $B = (143.5 \pm 0.8)\,\mu$G, which is below the equipartition value. The errors of the fit parameters, which are probably underestimated, depend on the additional ad-hoc systematic uncertainty added to the flux points, and hence they need to be taken with a grain of salt. When comparing the result of Meyer et al. (2010) with the one presented here we note that a higher value of the B-field is preferred compared to the 2010 paper in order to reproduce the MAGIC data around the IC peak. The higher quality (i.e. smaller error bars) of the *Fermi*-LAT data together with the MAGIC data show a rather flat peak now, which cannot be re-

produced in the model. If we would repeat the exact procedure from the 2010 paper and only use the updated *Fermi*-LAT data, we would find a lower B-field and the model would undershoot the MAGIC data at almost all energies. We, therefore, conclude that the constant *B*-field model cannot reproduce the flat peak of the IC SED. For energies above the peak, the predicted spectrum is too soft with too little curvature as compared to the new MAGIC data.

4.2. Time-dependent model

The time-dependent, leptonic spectral model for an isolated PWN (Martín et al. 2012; Torres et al. 2013a,b) was also considered. Such model solves the diffusion-loss equation numerically devoid of any approximation, considering synchrotron, IC and Bremsstrahlung energy losses. For the IC losses, the Klein-Nishina cross section is used. Escaping particles due to Bohm diffusion are also taken into account. The injection spectrum of the wind electrons follows a broken power law normalized using the spin-down power of the pulsar and the magnetic fraction[6]. The 1D uniform magnetic field is evolved by solving the magnetic field energy conservation, including its work on the environment (Torres et al. 2013b). Considering the young

---

[6]The magnetic fraction is the percentage of the spin down that goes into the magnetic field.

Figure 5: *On the left:* The overall spectral energy distribution of the Crab Nebula from radio to γ rays. Lines are best fit results based on Martín et al. (2012) (MTR), see text for details. The thin lines show individual components of the photon spectrum (see the inlay), and the thick blue line identifies the overall emission. Historical data (brown) are from Meyer et al. (2010), *Fermi*-LAT data (pink) are from Buehler et al. (2012), and the VHE data are from this work. *On the right:* Zoom in the γ-ray regime.

age of the remnant, the nebula was treated as freely expanding. The magnetic fraction of the nebula (η) was assumed constant along the evolution, and it was used to define the time-dependent magnetic field. The model here is essentially the same as the one shown in Torres et al. (2013a) except for the incorporation of a more precise dynamical evolution to fix the nebula radius taking into account the variation of the spin-down power in time. In particular, the evolution of the radius of the nebula was calculated solving numerically equation 25 in van der Swaluw et al. (2001). All the other time dependent parameters were left free to evolve with the PWN. The resulting electron population was used to compute the synchrotron, IC from CMB, far infrared (FIR), and near infrared (NIR) photon fields, as well as the synchrotron self-Compton (SSC) and bremsstrahlung spectra.

The results obtained by our qualitative fit are shown in Figure 5, whereas the parameter values are listed in Table 3. The free parameters of the fit consist of the definition of the environment −essentially, the target photon fields with which the electrons in the nebula interact− and of the wind electron spectrum −given by fitting the break and computing the time-dependent maximum Lorentz factor (the latter is a result of requesting that the Larmor radius be smaller than the termination shock) and the two slopes of the assumed broken power law−, and the mag-

netic field properties. The other parameters are fixed or strongly constrained. Since the fit is qualitative (we are aware that by having many simplifications the model can only be considered as qualitative description of the nebula), we do not provide uncertainties on the fit parameters. We find that a low magnetic fraction of the nebula (of only a few percent) with a magnetic field of approx. $80\,\mu$G provides a good fit to the nebula measurements at the current age. Such magnetic field strength is also motivated from morphological MHD studies (Volpi et al. 2008).

We note some caveats regarding this model. It includes no structural information: the size of the synchrotron sphere is taken as the size of the nebula itself, at all frequencies as in, e.g., Bucciantini et al. (2011) or in Tanaka & Takahara (2010). This is not the case for Crab though: the size of the nebula decreases towards the optical frequencies, being always smaller than the one obtained from the use of a dynamical free expansion solution. For instance, Hillas et al. (1998) use a radius of approximately $0.4\,$pc up to $0.02\,$eV, and slightly smaller for larger energies. If this energy-dependent size of the synchrotron nebula is adopted (one-zone spheres of different sizes at different frequencies), the SSC emission would be overproduced. A full description of such a rich data set requires a more detailed model that, in addition to being time dependent, treats the morphology

10

Table 3: Fit parameters for the time-dependent model obtained with the new data points given by *MAGIC*. The definition of the parameters can be found in Martín et al. (2012).

Magnitude	Crab Nebula
Pulsar magnitudes	
P (ms)	33.40
$\dot{P}$ (s s^{-1})	4.21×10^{-13}

w_{CMB} (eV cm^{-3})	0.25

at different frequencies using a multi-zone, multi-dimensional approach.

5. Conclusions

We presented a long term data set of the Crab Nebula taken with the MAGIC telescopes between October 2009 and April 2011. We derived an unprecedented differential energy spectrum of the Crab Nebula covering almost three decades in energy, from 50 GeV up to 30 TeV. The energy spectrum in this range is clearly curved and matches well both with the *Fermi*-LAT spectrum at lower energies and with the previous Crab Nebula measurements by Whipple, HEGRA, H.E.S.S. and early MAGIC-I data. The resulting IC peak is broad and rather flat in the energy range from 10 GeV to 200 GeV. We consider the joint MAGIC–*Fermi*-LAT fit to yield the most robust measurement of the IC peak position thanks to the large lever arm of the fit (four orders in magnitude in energy). We can narrow down the best peak position to be at (53 ± 3) GeV. However, the bad fit quality of the log-parabola fit shows that it is not a good representation of the Inverse Compton peak of the Crab Nebula. The MAGIC spectrum extends up to 30 TeV but we cannot distinguish between a power law tail extending up to 80 TeV (HEGRA, Aharonian et al. 2004) and a spectral cutoff at around 14 TeV (H.E.S.S., Aharonian et al. 2006). Independent from the nature of this discrepancy, if spectral variability or not, the statistics of the MAGIC data set, together with the systematic uncertainty, does not allow to draw any conclusion on this issue. We also show that the light curve of the Crab Nebula above 300 GeV is stable within the statistical and systematic uncertainties on the daily basis ($\sim 12\%$) during the considered period. Flux stability on longer time scales, as well as data taken simultaneously with the Crab flares will be discussed elsewhere.

The statistical precision of the MAGIC data set, spanning for the first time from 50 GeV to 30 TeV, allows for a detailed test of the two state-of-the-art Crab Nebula models. The conclusion, led by previous data sets, that simple model hypotheses

can account for the observed spectral shape, have to be revisited now in the light of the new results presented in this work. The constant B-field model (Meyer et al. 2010) leads to a rather poor fit to the new VHE measurements, mostly troubled by the broadness of the observed IC peak. Most probably this implies that the assumption of the homogeneity of the magnetic field inside the nebula is incorrect. On the other hand, the time dependent 1D model by Martín et al. (2012) can satisfactorily reproduce the VHE data up to few TeV under the assumptions of a low magnetic field of less than hundred μG. However, this model fails to provide a good fit of the new spectral data if the observed morphology of the nebula (smaller size at shorter wavelengths, as in Hillas et al. 1998) is adopted. Therefore, we conclude that more theoretical work on the Crab Nebula modeling must be done to simultaneously fit the observed morphology and the spectral energy distribution. The broad-band Inverse Compton spectrum is in principle sensitive to the spatial structure of the magnetic field and hence can be used for future models.
