(Received 29 October 2014; published 3 March 2015)

The strange contribution to the electric and magnetic form factors of the nucleon is determined at a range of discrete values of Q^2 up to 1.4 GeV^2 . This is done by combining a recent analysis of lattice QCD results for the electromagnetic form factors of the octet baryons with experimental determinations of those quantities. The most precise result is a small negative value for the strange magnetic moment: $G_M^s(Q^2 = 0) = -0.07 \pm 0.03 \mu_N$. At larger values of Q^2 both the electric and magnetic form factors are consistent with zero to within 2 standard deviations.

A quantitative determination of the contribution of nonvalence flavor quarks to nucleon observables remains a fundamental challenge of hadronic physics. Since such contributions must arise entirely through interactions with the vacuum, their sign and magnitude provide key information regarding the nonperturbative structure of the nucleon; their determination within nonperturbative QCD constitutes a test of a level of importance comparable to that of the Lamb shift for QED. Strange quarks, as the lightest sea-only flavor, are expected to play the largest role.

Recent years have seen extensive experimental efforts directed at measuring strangeness in the nucleon. The strange electromagnetic form factors in particular have been determined from experiments at JLab (G0, HAPPEX) [1–7], MIT-Bates (SAMPLE) [8,9], and Mainz (A4) [10–12]. Probing a range of values of Q^2 up to $\approx 0.94 \text{ GeV}^2$, the combined data sets constrain the strange contribution to the nucleon form factors to be less than a few percent but are consistent with zero to within 2σ [13]. The status of the strange form factors from theory is less clear; predictions from various quark models cover a very broad range of values [14–19], and the large computational cost of all-to-all propagators has so far limited direct lattice QCD studies to large pion masses and single volumes [20,21].

In this Letter we determine the strangeness contributions to the nucleon electromagnetic form factors indirectly at a

range of values of Q^2 currently unattainable through direct experimental measurement. Under the assumption of charge symmetry, one can combine experimental measurements of the total nucleon form factors with lattice QCD determinations of the connected (or “valence” quark) contributions to deduce the disconnected (or “sea” quark) components [22]. This method has been applied previously to determine the strange magnetic form factor at $Q^2 = \{0, 0.23\} \text{ GeV}^2$ [23,24] and the strange electric form factor at $Q^2 = 0.1 \text{ GeV}^2$ [25] from quenched lattice QCD results. In this work we are able to perform a complete study using a recent analysis of dynamical $2 + 1$ -flavor lattice QCD simulations [26,27] to determine both the strange electric and magnetic form factors at six discrete values of Q^2 up to 1.4 GeV^2 .

The lattice results used here are an extension of those reported in Refs. [26,27]; we include two independent sets of $2 + 1$ -flavor simulations at different values of the finite lattice spacing a . The lattice volumes are $L^3 \times T = 32^3 \times 64$ and $48^3 \times 96$, and the lattice spacings are $a = 0.074(2) \text{ fm}$ and $0.062(2) \text{ fm}$ (set using various singlet quantities [28,29]) for the two sets, respectively. The particular values used as input here are the connected quark contributions to the electric and magnetic form factors of the outer-ring octet baryons after extrapolation to infinite volume and to the physical pseudoscalar masses. That extrapolation, detailed in Refs. [26,27], is performed

using a formalism based on connected chiral perturbation theory [30,31].

The extraction of the strange electromagnetic form factors from the extrapolated lattice results follows the procedure introduced in Refs. [32,33]. Under the assumption of charge symmetry, which is an exact symmetry of QCD if one neglects QED and the light quark mass difference (i.e., assuming $m_u = m_d$), one may express the electromagnetic form factors of the proton and neutron as [22]

$$p = e^u u^p + e^d d^p + O_N, \quad (1)$$

$$n = e^d u^p + e^u d^p + O_N. \quad (2)$$

Here, p and n denote the physical (electric or magnetic) form factors of the proton and neutron and u^p and d^p represent the connected u and d quark contributions to the proton form factor. The disconnected quark loop term, O_N , may be decomposed into individual quark contributions:

$$O_N = \frac{2}{3} {}^\ell G^u - \frac{1}{3} {}^\ell G^d - \frac{1}{3} {}^\ell G^s, \quad (3)$$

$$= \frac{{}^\ell G^s}{3} \left(\frac{1 - {}^\ell R_d^s}{{}^\ell R_d^s} \right), \quad (4)$$

where charge symmetry has been used to equate ${}^\ell G^u = {}^\ell G^d$ and the ratio of s to d disconnected quark loops is denoted by ${}^\ell R_d^s = {}^\ell G^s / {}^\ell G^d$.

Rearranging Eqs. (1), (2), and (4) to isolate the strange quark loop contribution ${}^\ell G^s$ yields two independent expressions which are rigorous consequences of QCD under the assumption of charge symmetry:

$${}^\ell G^s = \left(\frac{{}^\ell R_d^s}{1 - {}^\ell R_d^s} \right) [2p + n - u^p], \quad (5)$$

$${}^\ell G^s = \left(\frac{{}^\ell R_d^s}{1 - {}^\ell R_d^s} \right) [p + 2n - d^p]. \quad (6)$$

In principle, given a suitable estimate of ${}^\ell R_d^s$, these expressions may be simply evaluated; the total form factors p and n are well known experimentally and the connected contributions u^p and d^p may be calculated on the lattice.

This procedure relies on the assumption that the difference between the experimental numbers and the connected lattice simulation results for the form factors may be entirely attributed to contributions from disconnected quark loops, i.e., that all other systematic effects are under control. In order to be able to estimate any as-yet undetermined lattice systematics, we average Eqs. (5) and (6) resulting in a form where only the connected contribution to the combination $(u^p + d^p)_{\text{conn.}}$ needs to be determined from the lattice:

$${}^\ell G^s = \left(\frac{{}^\ell R_d^s}{1 - {}^\ell R_d^s} \right) \left[\frac{3}{2} (p + n) - \frac{1}{2} (u^p + d^p)_{\text{conn.}} \right]. \quad (7)$$

Relaxing the assumption of exact charge symmetry in the valence sector would result in an additional term $+\frac{3}{2} G^{u,d}$ (where, in the notation of Ref. [34], $G^{u,d}$ is the systematic charge symmetry violation (CSV) uncertainty affecting experimental determinations of the strange form factors) appearing within the square brackets of Eq. (7). For low values of Q^2 in particular, where $({}^\ell R_d^s / (1 - {}^\ell R_d^s))$ is small, this systematic thus affects our extraction of the strange form factors considerably less than it impacts on experimental determinations of these quantities, where the assumption of good charge symmetry is also standard. Taking the values of $G^{u,d}$ from Ref. [34] as a systematic uncertainty would increase our error bands by less than 10%. Furthermore, a recent reevaluation of $G^{u,d}$ using relativistic chiral perturbation theory with a more realistic ω -nucleon coupling [35] found a significant reduction in $G^{u,d}$, suggesting that the assumption of good charge symmetry has a negligible effect on our results. For values of Q^2 larger than about 0.3 GeV² there have been few calculations of the relevant CSV quantities to date. However, a lattice-based determination using the same simulations used for this work, independent of assumptions regarding strangeness, suggests that CSV effects remain negligible for this calculation of the strange form factors across the entire Q^2 -range of relevance [36].

We discuss in turn each of the three inputs into Eq. (7): (i) The lattice values for $(u^p + d^p)_{\text{conn.}}$. (ii) The experimental p and n form factors. (iii) The ratio ${}^\ell R_d^s = {}^\ell G^s / {}^\ell G^d$. As described previously, the lattice results used for the connected u and d quark contributions to the proton electric and magnetic form factors, u^p and d^p , are an extended set of those presented in Refs. [26,27]. Both statistical uncertainties and systematic effects resulting from the chiral and infinite-volume extrapolations, including an estimate of the model-dependence, are accounted for. We additionally allow for any unknown systematics on the combination $(u^p + d^p)_{\text{conn.}}$ by estimating that such effects will be similar in magnitude for the isovector combination $(u^p - d^p)_{\text{conn.}}$ which may be directly compared with experiment. Because disconnected contributions in the total form factors cancel in the combination $(p - n)$, the difference $(u^p - d^p)_{\text{Latt.}} - (p - n)_{\text{Exp.}}$ provides an estimate of any unaccounted-for uncertainty in the lattice simulation results. We take the largest value of this difference, evaluated at a range of discrete simulation values of Q^2 , as a conservative estimate.

This procedure is followed for both the electric and magnetic form factors. The additional uncertainty included in this fashion is significant and larger than the statistical uncertainty in the determination of the strange magnetic form factor. For the electric form factor it is a modest contribution of a size similar to or smaller than the statistical uncertainty.

The total proton and neutron electromagnetic form factors p and n are taken from the parameterizations of experimental results by Kelly [37] and Arrington and Sick [38] (the latter is used only on its quoted range of validity, $Q^2 < 1$ GeV²). The entire calculation, including the additional estimate of lattice systematics, is performed using

FIG. 1. Loop diagrams which are included in the estimate of ℓR_d^s from effective field theory. Figure 1(b) is included for the electric form factor only. The solid, dashed and wavy lines denote octet baryons, mesons, and photons, respectively.

each parameterization. The average central value of the two sets of results is taken as the best estimate of the strange form factors. Half of the difference between the two central values is included as an estimate of the parameterization-dependent uncertainty. This contribution to the uncertainty is small.

We derive an estimate for the disconnected quark-loop ratio $\ell R_d^s = \ell G^s / \ell G^d$ using a model based on chiral effective field theory, as also done in Refs. [23–25]. In that formalism ℓR_d^s is given by the ratio of loop diagram contributions to the electromagnetic form factors, where the relevant loop integrals are weighted by the appropriate “disconnected” chiral coefficients for the s and d quarks [24,25,30].

The primary loop diagram relevant to this calculation is depicted in Fig. 1(a). For the electric form factor in particular, a higher-order diagram [Fig. 1(b)] is important as it makes a significant contribution of the opposite sign to that of Fig. 1(a), resulting in a large cancellation. While to the order of the calculation in Refs. [26,27] this term contributes a constant to $G_E(Q^2)$ (enforcing charge conservation at $Q^2 = 0$), this is not a good approximation for the large Q^2 values considered in this work.

For this reason we include Fig. 1(b), with an estimate of its Q^2 dependence, explicitly in our calculation of ℓR_d^s for the electric form factor. This is achieved by calculating the diagram in heavy-baryon chiral perturbation theory and modeling the Q^2 dependence of the photon-baryon vertex based on the lattice results of Ref. [26].

The uncertainty in the ratio ℓR_d^s is estimated by additionally including loops with decuplet-baryon intermediate states, as well as allowing the dipole mass parameter Λ used in the finite-range regularization scheme to vary between 0.6 and 1.0 GeV [39–41]. The resulting values for ℓR_d^s are shown in Fig. 2.

Finally, the results of this analysis [using Eq. (7)] for the strange electric and magnetic form factors of the proton at nonzero Q^2 are summarized in Table I and are displayed in Fig. 3 alongside the latest experimental determinations of those quantities. All results (away from $Q^2 = 0$) are consistent with zero to within 2σ . The results for the strange magnetic form factor favor negative values which are consistent with recent experimental results. For the electric form factor, the two independent analyses based on lattice QCD simulations at different lattice spacings and

FIG. 2 (color online). Estimate of ℓR_d^s from effective field theory with finite-range regularization for the electric (dashed green line) and magnetic (solid blue line) form factors.

volumes are inconsistent at 1σ . As a result, simple estimates of the strange electric charge radius of the proton using a straight-line fit in Q^2 to the lowest- Q^2 result for G_E^s give results with opposite signs for the two analyses:

$$\langle r_E^2 \rangle^s = \begin{cases} 0.0086(79) \text{ fm}^2, & a = 0.074(2) \text{ fm} \\ -0.0114(88) \text{ fm}^2, & a = 0.062(2) \text{ fm} \end{cases} \quad (8)$$

Although we cannot make a conclusive statement without additional simulation results, we expect that this difference is dominated by statistical fluctuations.

Since experimental determinations of the strange form factors are obtained as linear combinations of G_E^s and G_M^s we also display results at the lowest values of the momentum transfer, $Q^2 = 0.26 \text{ GeV}^2$ and 0.17 GeV^2 for the $a = 0.074(2) \text{ fm}$ and $0.062(2) \text{ fm}$ simulation sets respectively, in the G_M^s - G_E^s plane in Fig. 4. The available experimental results for similar values of Q^2 appear on this figure as ellipses. Both present calculations are consistent with experiment to within 2σ .

Using the additional information available from experiment at $Q^2 = 0$, where the hyperon form factors have been

FIG. 3 (color online). Strange contribution to the magnetic [3(a)] and electric [3(b)] form factors of the proton, for strange quarks of unit charge. The blue circles and purple squares show the results of independent analyses based on lattice simulations with scales $a = 0.074(2)$ fm and $0.062(2)$ fm, respectively. The experimental results (red stars) are taken from Refs. [2,4,5,8,9,12].

measured [42], we also determine the strange contribution to the proton magnetic moment. We rearrange Eqs. (5) and (6), using the assumption of charge symmetry, to express the nucleon strange magnetic moment in terms of the hyperon moments [22,33]:

$$\ell G^s = \left(\frac{\ell R_d^s}{1 - \ell R_d^s} \right) \left[2p + n - \frac{u^p}{u^\Sigma} (\Sigma^+ - \Sigma^-) \right], \quad (9)$$

$$\ell G^s = \left(\frac{\ell R_d^s}{1 - \ell R_d^s} \right) \left[p + 2n - \frac{u^n}{u^\Xi} (\Xi^0 - \Xi^-) \right]. \quad (10)$$

This rearrangement minimizes the propagation of lattice systematics as only ratios of form factors must be determined from lattice QCD.

The ratios u_M^p/u_M^Σ and u_M^n/u_M^Ξ of connected up quark contributions to the hyperon form factors, at a range of nonzero values of the momentum transfer Q^2 , are taken from the lattice QCD analyses described earlier [26,27]. We determine the $Q^2 = 0$ values needed here using a linear extrapolation in Q^2 , with an additional experimental constraint provided by the equality of Eqs. (9) and (10):

$$\frac{u_M^p}{u_M^\Sigma} = \frac{u_M^n}{u_M^\Xi} \left(\frac{\mu_{\Xi^0} - \mu_{\Xi^-}}{\mu_{\Sigma^+} - \mu_{\Sigma^-}} \right) + \left(\frac{\mu_p - \mu_n}{\mu_{\Sigma^+} - \mu_{\Sigma^-}} \right), \quad (11)$$

FIG. 4 (color online). Comparison of the results of this work to 1σ (red ellipse) at $Q^2 = 0.26$ GeV² for $a = 0.074(2)$ fm and (orange ellipse) at $Q^2 = 0.17$ GeV² at $0.062(2)$ fm with available experimental results at similar values of Q^2 . The dark and pale green ellipses show 1σ and 2σ results from the A4 Collaboration at $Q^2 = 0.23$ GeV² [11] while the blue ellipses show G0 Collaboration results close to $Q^2 = 0.23$ GeV² [1,2].

where μ_B denotes the experimental magnetic moment of the baryon B [42]. The fit is performed to the lattice results where $Q^2 < 1$ GeV², which display qualitatively linear behavior and for which the linear-fit $\chi^2/\text{degrees of freedom}$ is acceptable given the constraint of Eq. (11). Fitting to one less data point does not change the results to the precision quoted.

The best estimates of the $Q^2 = 0$ ratios of connected contributions to the baryon magnetic form factors are

$$\left[\frac{u_M^p}{u_M^\Sigma}, \frac{u_M^n}{u_M^\Xi} \right] = \begin{cases} [1.096(16), 1.239(90)], & a = 0.074(2) \text{ fm} \\ [1.095(17), 1.222(98)], & a = 0.062(2) \text{ fm} \end{cases}, \quad (12)$$

where the two sets of results correspond to our two independent analyses using lattice QCD simulation results at different lattice spacings and volumes as described earlier. These full-QCD numbers align remarkably well with those determined in Ref. [23], given that that analysis was based on quenched lattice simulation results after the application of a theoretical “unquenching” formalism [40].

The resulting values for the strange magnetic moment [from Eqs. (9) and (10)], conventionally defined without the charge factor, are

$$G_M^s(Q^2 = 0) = \begin{cases} -0.071(13)(25)(4)\mu_N, & a = 0.074(2) \text{ fm} \\ -0.073(14)(26)(4)\mu_N, & a = 0.062(2) \text{ fm} \end{cases}. \quad (13)$$

The first uncertainty is propagated from the lattice simulation results, the second, dominant, contribution comes from the ratio ℓR_d^s , and the last is that from the experimental determination of the magnetic moments [42]. Clearly, the results of our analysis using two independent calculations

performed at different lattice spacings and volumes are in excellent agreement.

Our final result for the strange magnetic moment of the proton, $G_M^s(Q^2 = 0) = -0.07 \pm 0.03\mu_N$, is nonzero to 2σ and an order of magnitude more precise than the closest experimental results. The results reported at the values of Q^2 above 0.6 GeV^2 are the first determinations, experimental or based on lattice QCD, in that region. At present they cannot be distinguished from zero, but the uncertainties constrain their actual values to be very small.

We thank D.B. Leinweber for a careful and critical reading of the manuscript. The numerical configuration generation was performed using the BQCD lattice QCD program [43] on the IBM BLUEGENE-Q using DIRAC 2 resources (EPCC, Edinburgh, UK), the BlueGene P and Q at NIC (Jülich, Germany) and the Cray XC30 at HLRN (Berlin-Hannover, Germany). The BlueGene codes were optimized using Bagel [44]. The Chroma software library [45] was used in the data analysis. This work was supported by the EU Grants No. 283286 (HadronPhysics3), No. 227431 (Hadron Physics2), and by the University of Adelaide and the Australian Research Council through the ARC Centre of Excellence for Particle Physics at the Terascale and grants FL0992247 (A. W. T.), FT120100821 (R. D. Y.), DP140103067 (R. D. Y. and J. M. Z.) and FT100100005 (J. M. Z.).
