

Measurement of Dijet Production in Diffractive Deep-Inelastic ep Scattering at HERA

H1 Collaboration

Abstract

A measurement is presented of single- and double-differential dijet cross sections in diffractive deep-inelastic ep scattering at HERA using data collected by the H1 experiment corresponding to an integrated luminosity of 290 pb^{-1} . The investigated phase space is spanned by the photon virtuality in the range of $4 < Q^2 < 100 \text{ GeV}^2$ and by the fractional proton longitudinal momentum loss $x_P < 0.03$. The resulting cross sections are compared with next-to-leading order QCD predictions based on diffractive parton distribution functions and the value of the strong coupling constant is extracted.

1 Introduction

In deep-inelastic scattering (DIS), diffractive reactions of the type $ep \rightarrow eXY$, where X is a high-mass hadronic final state and Y is either the elastically scattered proton or its low-mass excitation, represent about 10% of the events at HERA and provide rich experimental input for testing quantum chromodynamics (QCD) in the diffractive regime. These processes can be understood as probing by a virtual photon emitted from the beam lepton a net colour singlet carrying vacuum quantum numbers (a pomeron) [1, 2]. Due to the colourless exchange the systems X and Y are separated by a rapidity interval free of hadronic activities. In these processes at least one hard scale is involved such that perturbative QCD (pQCD) can be applied.

According to the QCD collinear factorisation theorem [3], calculations of diffractive cross sections factorise into process dependent hard scattering coefficient functions and a set of process independent diffractive parton distribution functions (DPDFs). While the hard scattering coefficient functions are calculable in pQCD, the DPDFs have to be determined from QCD fits to the measured inclusive diffractive cross sections. In such QCD fits [4], DGLAP evolution [5–7] of the DPDFs is assumed. The QCD factorisation theorem is proven to hold for inclusive and dijet diffractive processes [8], assuming high enough photon virtuality such that higher twist effects can be neglected. The DPDFs are experimentally determined by assuming an additional factorisation of the DPDFs dependence on the scattered proton momentum from the dependence on the other variables, ascribed to the structure of the colourless exchange. This assumption is known as proton vertex factorisation. A pomeron flux in the proton is introduced and universal parton densities are attributed to the diffractively exchanged object. Many measurements of diffraction in DIS suggest the validity of the proton vertex factorisation assumption in DIS [4, 9–11].

In leading order the inclusive diffractive cross section in ep scattering is proportional to the charge-squared weighted sum of the quark distribution functions in the pomeron, while its gluon content can be determined only indirectly via scaling violations. As events with two jets (dijets) are readily produced in gluon-induced processes, measurements of diffractive dijet cross sections are sensitive to the value of the strong coupling α_s and to the gluon content of the pomeron. The production of dijets in diffractive DIS has previously been studied at HERA using either the large rapidity gap (LRG) method [12–14] or by direct detection of the outgoing proton [15].

In this paper cross section measurements of dijet production in diffractive ep scattering are presented, based on data collected in the years 2005–2007 with the H1 detector at HERA. Diffractive events are selected by means of the LRG method, requiring a clear separation in rapidity of the final state systems X and Y . The measured cross sections are compared to next-to-leading order (NLO) QCD predictions evaluated with input DPDFs determined in previous inclusive diffractive measurements by the H1 collaboration [4].

The present analysis is based on the full HERA-II data sample resulting in significantly increased statistics with respect to previous analyses. Furthermore, the cross sections are determined using a regularised unfolding procedure which fully accounts for efficiencies, migrations and correlations among the measurements. The measured dijet cross sections are used to extract the strong coupling constant α_s in diffractive DIS processes for the first time.

2 Kinematics

Figure 1: Leading order diagram for the production of dijets in diffractive DIS.

A leading order (LO) diagram of boson-gluon fusion, which is the dominant process for the production of two jets in diffractive DIS, is depicted in Figure 1. The incoming electron¹ of four-momentum k interacts with the incoming proton of four-momentum p via the exchange of a virtual photon of four-momentum $q = k - k'$. The outgoing proton or its low-mass dissociation state carries four-momentum p' . The DIS kinematics is described by the following set of variables:

$$Q^2 = -q^2 = (k - k')^2, \quad x = \frac{Q^2}{2p \cdot q}, \quad y = \frac{p \cdot q}{p \cdot k}, \quad (1)$$

where Q^2 , x and y denote the photon virtuality, the Bjorken- x variable and the inelasticity of the process, respectively. Conservation laws stipulate the relation $Q^2 = xys$, where s stands for the ep centre-of-mass energy squared.

The kinematics of the diffractive exchange is described in terms of the additional quantities

$$x_P = \frac{q \cdot (p - p')}{q \cdot p}, \quad t = (p - p')^2 \quad (2)$$

with x_P and t being the longitudinal momentum fraction of the incoming proton carried by the pomeron and the squared four-momentum transfer at the proton vertex, respectively. The fractional longitudinal momentum of the pomeron transferred to the dijet system is given by

$$z_P = \frac{q \cdot v}{q \cdot (p - p')} = \frac{x}{x_P}, \quad (3)$$

where v is the four-momentum of the parton entering the hard interaction.

¹In this paper the term "electron" is used generically to refer to both electrons and positrons.

3 Monte Carlo Models and Fixed Order QCD Calculations

The RAPGAP event generator [16] allows for the simulation of processes $ep \rightarrow eXY$ including both leading (pomeron) and sub-leading (reggeon) exchanges. Assuming the proton vertex factorisation, the parton densities obtained in the previous QCD analysis of inclusive diffractive data (H12006 Fit-B) [4] are convoluted with leading order QCD matrix elements. Higher order QCD radiation effects are modelled via initial and final state parton showers in the leading-log approximation [17]. Hadronisation is accounted for by making use of the Lund string model [18] as implemented in PYTHIA [19].

Within the diffractive selection based on the LRG method, the system Y may also be a low mass dissociative system. Proton dissociation events are simulated in the range of $M_Y < 20$ GeV using the RAPGAP event generator, where M_Y is the mass of the system Y . Resonant contributions together with the continuum part of the M_Y distribution are modelled similarly to the DIFFVM event generator [20]. A small admixture of resolved γ^*p scattering is included in fixed LO mode of jet production in the low Q^2 region [21]. The resolved photon contribution is simulated with the RAPGAP event generator using the SaS-G PDF set [22] as the input PDF of the photon. QED radiation effects are simulated with the HERACLES [23] program interfaced to RAPGAP. Besides the Born level contribution, the simulated cross sections include contributions from initial and final state emission of real photons from the electron, from vertex corrections as well as from self energy diagrams. As the H12006 Fit-B DPDF set has previously been observed to underestimate the data in the low Q^2 region, a weighting is applied for $Q^2 < 7 \text{ GeV}^2$, parametrised as the ratio of the data in [4] to the Monte Carlo expectation based on the H12006 Fit-B DPDF set.

Background arising from non-diffractive DIS processes is also simulated with the RAPGAP event generator using its inclusive mode together with the CTEQ6L PDF set [24].

The MC simulation is used to correct the data for detector effects. The generated events undergo the full GEANT [25] simulation of the H1 detector and are analysed in the same way as the real data. In order to describe the measured distributions, the diffractive MC is reweighted in several variables as discussed in 4.4.

QCD predictions of the dijet cross sections at the parton level are evaluated at NLO using the NLOJET++ program [26, 27]. The NLO pQCD predictions are calculated in the $\overline{\text{MS}}$ -scheme with five active flavors. The two-loop approximation of the renormalisation group equation is used for the running of the strong coupling constant with a coupling strength of $\alpha_s(M_Z) = 0.118$. The cross sections are evaluated in intervals of x_P , effectively replacing the beam proton by a pomeron (slicing method). The H12006 Fit-B DPDF set is used in the calculation. The renormalisation and factorisation scales μ_r and μ_f are provided by the photon virtuality and the average transverse momentum of the leading and sub-leading jet, $\langle p_T^* \rangle$, in the γ^*p centre-of-mass frame and are defined as $\mu_r = \mu_f = \sqrt{\langle p_T^* \rangle^2 + Q^2}$. The uncertainty on the prediction due to missing higher orders is estimated by simultaneous variation of the renormalisation and factorisation scales by factors of 0.5 or 2. An uncertainty on the NLO prediction from the experimental uncertainties on the DPDF set is obtained using the eigenvector decomposition of the uncertainties of the H12006 Fit-B DPDF set. This uncertainty is propagated to the NLO prediction using

the sign-improved formulae for error propagation [28]. A significant contribution to the uncertainty of the H12006 Fit-B set originates from the restriction of the input data to $z_P < 0.8$ and the extrapolation of the DPDF to $z_P > 0.8$.

Whereas the measured cross sections are compared to the predictions obtained by the slicing method, an alternative method of adapting the NLO calculations for diffractive DIS is used in the α_s extraction. In order to provide theory predictions with different values of $\alpha_s(M_Z)$, the fastNLO method [29–31] is used. Cross section predictions are obtained by folding tabulated matrix elements obtained from NLOJET++ [26,27] with the DPDF parametrisation. The matrix elements are determined as a function of the observable of interest, the factorisation scale μ_F and the convolution variable x . The relation $x = x_P z_P$ is used when folding with the DPDF. This way predictions can be obtained for different choices of DPDFs, of α_s and of the renormalisation and the factorisation scales without having to calculate the matrix elements all over again. Settings identical to the slicing method are used for parameters such as renormalisation and factorisation scales or DPDF set and very good numerical agreement with the slicing method is found. The uncertainty on the prediction due to missing higher orders is estimated by varying the scales by a factor f , where $0.5 < f < 2$.

Since the measured cross sections are given at the level of stable hadrons, the QCD predicted cross sections have to be corrected for effects of initial and final state parton showers, hadronisation and fragmentation. These corrections are determined for each of the measured cross sections as the ratio of hadron to parton level cross sections, predicted with the RAPGAP event generator. Two distinct models of parton showers, the leading-log approximation and the colour dipole model as implemented in the ARIADNE program [32], are used in this calculation. In each measurement interval the resulting correction is taken as the average of the values predicted by the two models and the uncertainties on the correction factors are taken as half the difference of the two predictions. The hadron level cross sections are on average about 5% higher than the parton level cross sections. The total uncertainty on the NLO QCD predictions is obtained as the quadratic sum of the uncertainties from scale variation, DPDF fit and hadronisation uncertainties.

4 Experimental Technique

4.1 H1 detector

A detailed description of the detector can be found elsewhere [33]. Here only those detector components relevant for the present analysis are briefly described. A right-handed coordinate system with the origin at the nominal interaction point and with the z -axis pointing in the proton beam direction is conventionally chosen as the laboratory frame. The polar angle θ is measured with respect to the z -axis, while the direction in the x - y plane is defined by the azimuthal angle ϕ . The pseudorapidity is defined as $\eta = -\ln \tan(\theta/2)$.

The liquid argon (LAr) sampling calorimeter [34] is located inside a 1.15 T solenoidal field and covers the polar angular range $4^\circ < \theta < 154^\circ$. The energy resolutions for electromagnetic and hadronic showers as determined in test beam measurements [35, 36] are $\sigma(E)/E \propto$

$11\%/\sqrt{E/\text{GeV}} \oplus 1\%$ and $\sigma(E)/E \propto 50\%/\sqrt{E/\text{GeV}} \oplus 2\%$, respectively. The energy and scattering angle of the scattered electron is measured in a scintillating fibre calorimeter SpaCal [37,38] with a resolution of $\sigma(E)/E \propto 7\%/\sqrt{E/\text{GeV}} \oplus 1\%$. The precision of the energy scale is 1% covering the polar angular range $154^\circ < \theta_{e'} < 174^\circ$. The measurement of the polar angle of the scattered electron $\theta_{e'}$ is improved by means of a backward proportional chamber (BPC). The precision of the polar angle measurement is 1 mrad.

Trajectories of charged particles are measured with the central tracking detector (CTD) located inside the LAr calorimeter with a transverse momentum resolution of $\sigma_{p_T}/p_T \simeq 0.2\% \cdot p_T/\text{GeV} \oplus 1.5\%$ in the polar angular range of $15^\circ < \theta < 165^\circ$.

The information from CTD and LAr is used for the reconstruction of the system X . The interaction vertex position is determined event-by-event using the particle trajectories measured in CTD.

The following H1 forward detectors are used in the LRG selection of diffractive events. The forward muon detector (FMD) consists of six proportional chambers which are grouped into two three-layer sections separated by a toroidal magnet. Although the nominal coverage of FMD is $1.9 < \eta < 3.7$, particles with pseudorapidity up to $\eta \sim 6.5$ can be detected indirectly through their interactions with the beam transport system and detector support structures. The lead-scintillator Plug calorimeter is located at $z = 4.9$ m and covers the range $3.5 < \eta < 5.5$. The very forward region is covered by the forward tagging system (FTS) comprising scintillators surrounding the beam pipe. Only one station of FTS, situated at $z = 28$ m and covering the range $6.0 < \eta < 7.5$, is included in the present analysis.

The instantaneous luminosity is monitored based on the rate of the Bethe-Heitler process $ep \rightarrow ep\gamma$. The final state photon is detected by a photon detector located close to the beam pipe at $z = -103$ m. The precision of the integrated luminosity measurement is improved in a dedicated analysis of the QED Compton process [39].

4.2 Reconstruction of observables

The DIS observables Q^2 , x and y are reconstructed using the electron- Σ method [40]. Within this method, the photon virtuality Q^2 is reconstructed based on the measured four-momentum of the scattered electron, while the inelasticity y and Bjorken- x are determined making use of combined information from the hadronic final state (HFS) and the scattered electron.

The four-momenta of the particles attributed to HFS are reconstructed using an algorithm which combines information provided by the tracking system and the LAr calorimeter by avoiding double counting of hadronic energy [41,42]. The calibration of the HFS energy scale derived in [43] is applied. The performance of the calibration was studied by comparing the transverse momentum balance in data and MC in the kinematic domain of this analysis.

Jets are reconstructed in the γ^*-p centre-of-mass frame using the inclusive k_T jet algorithm [44] with the p_T recombination scheme as implemented in the FastJet program [45]. The jet distance parameter is set to $R = 1.0$. The transverse momenta and pseudorapidities of the

leading and sub-leading jets are denoted as $p_{T,1}^*$, η_1^* and $p_{T,2}^*$, η_2^* , respectively². The invariant mass of the final state system X is reconstructed as:

$$M_X = c(\eta_{max}) \sqrt{P_X^2}, \quad (4)$$

where P_X is the four-momentum of the system X obtained as a vector sum of all particles contained in the HFS. The MC simulation is used in order to derive the average correction for detector losses $c(\eta_{max})$, where η_{max} is the pseudorapidity of the most forward energy deposition above 800 MeV in the LAr calorimeter. The momentum fractions x_P and z_P are reconstructed as:

$$x_P = \frac{Q^2 + M_X^2}{ys} \quad (5)$$

and

$$z_P = \frac{Q^2 + M_{12}^2}{Q^2 + M_X^2}, \quad (6)$$

where M_{12} is the invariant mass of the dijet system.

Cross sections for dijet production in diffractive DIS are measured differentially with respect to the variables Q^2 , y , x_P , z_P , $p_{T,1}^*$, $p_{T,2}^*$, $\langle p_T^* \rangle = (p_{T,1}^* + p_{T,2}^*)/2$ and $\Delta\eta^* = |\eta_1^* - \eta_2^*|$.

4.3 Event selection

The measurement is based on the H1 data collected in the years 2005 to 2007 with a total integrated luminosity of 290 pb⁻¹. The nominal beam energies of the protons and electrons are $E_p = 920$ GeV and $E_e = 27.6$ GeV, respectively.

The longitudinal position of the reconstructed event vertex is restricted to the range $-35 < z_{vtx} < 35$ cm. DIS events are selected by the identification of the scattered electron in the backward calorimeter SpaCal. The isolated energy deposit of electromagnetic structure with the highest transverse momentum is identified as scattered electron and has to have a measured energy of at least 9.5 GeV.

Only events accepted by a trigger combining signals induced by the scattered electron in the SpaCal with minimum track information of the CTD are used in the analysis. The trigger efficiency related to the CTD condition is found to be 98%-99%, depending on the detector configuration and is reproduced by the MC simulation within 2%. The trigger efficiency related to the SPACAL condition is better than 99%.

Residual non-DIS background is dominated by photoproduction processes, where a hadron is misidentified as the scattered electron, whereas the true scattered electron escapes detection due to its small scattering angle. This background is reduced to a negligible level by demanding $35 < \sum_i (E - p_z)_i < 75$ GeV, where the sum runs over all HFS particles and the scattered electron candidate. Elastic QED Compton scattering $ep \rightarrow e\gamma p$ introduces another background contribution which is suppressed by rejecting configurations with two back-to-back clusters in SpaCal.

²Observables in the γ^* - p centre-of-mass frame are labelled with an asterisk.

Diffractive events are identified with the LRG method which requires an empty interval in rapidity between the systems X and Y . The low-mass system Y is produced at very large pseudorapidities and escapes detection. The diffractive signature is thus defined by the systems X (in the main detector) and Y (undetected). The energy of any cluster in the forward region of the LAr calorimeter is required to be below the noise level of 800 MeV, which is ensured by demanding $\eta_{max} < 3.2$. The variable η_{max} corresponds to the LAr cluster above the noise threshold which has the largest pseudorapidity. Information provided by the forward detectors FMD, FTS and the Plug calorimeter is used in order to extend the gap to rapidities beyond the LAr acceptance and in order to suppress the proton dissociation contribution. These detectors are required to show no signal above noise level [46]. At high momentum fractions x_P , the system X tends to extend into the direction of the outgoing system Y and the experimental separation of the systems X and Y is not possible. The LRG selection method is thus applicable only in the region of $x_P \lesssim 0.03$. The sample of DIS events satisfying the LRG criteria is dominated by the diffractive exchange, as the system X is isolated in the main part of the H1 detector, while the system Y escapes undetected down the beam pipe. The signal is dominated by proton-elastic processes, $ep \rightarrow eXp$, however, a small fraction of proton dissociation events is also accepted by the LRG selection. The LRG requirements impose restrictions on the mass and scattering angle of the hadronic system Y . These correspond approximately to the requirements $M_Y < 1.6$ GeV and $|t| < 1$ GeV². Migrations in these variables are modelled using MC simulations.

	Extended Analysis Phase Space	Measurement Cross Section Phase Space
DIS	$3 < Q^2 < 100 \text{ GeV}^2$ $y < 0.7$	$4 < Q^2 < 100 \text{ GeV}^2$ $0.1 < y < 0.7$
Diffraction	$x_P < 0.04$ LRG requirements	$x_P < 0.03$ $ t < 1 \text{ GeV}^2$ $M_Y < 1.6 \text{ GeV}$
Dijets	$p_{T,1}^* > 3.0 \text{ GeV}$ $p_{T,2}^* > 3.0 \text{ GeV}$ $-2 < \eta_{1,2}^{\text{lab}} < 2$	$p_{T,1}^* > 5.5 \text{ GeV}$ $p_{T,2}^* > 4.0 \text{ GeV}$ $-1 < \eta_{1,2}^{\text{lab}} < 2$

Table 1: Summary of the extended analysis phase space and the phase space for the dijet cross sections measurements.

Events are selected in a phase space which is extended compared to the measurement phase space in order to improve the precision of the measurement by accounting for migrations at the phase space boundaries. Events within the DIS phase space of $y < 0.7$ and $3 < Q^2 < 100 \text{ GeV}^2$ are selected. The events are required to have at least two jets in the pseudorapidity range $-2 < \eta_{1,2}^{\text{lab}} < 2$ and transverse momenta greater than 3 GeV in the γ^* - p centre-of-mass frame.

The measurement phase is defined by the DIS requirements of $0.1 < y < 0.7$ and $4 < Q^2 < 100 \text{ GeV}^2$. The pseudorapidity of jets is restricted in the laboratory frame to $-1 < \eta_{1,2}^{\text{lab}} < 2$ to ensure the jets to be contained well within the central detector. The transverse momenta of the leading and sub-leading jets are required to be larger than 5.5 GeV and 4.0 GeV, respectively. The extended phase space and the measurement phase space definitions are summarised in

table 1. The total number of events accepted by the LRG selection criteria together with the DIS and jet requirements is ~ 50000 and ~ 15000 for the extended and measurement phase space, respectively.

4.4 Corrections to the data

Cross sections at the level of stable hadrons are obtained from the measured event rates in data by applying corrections determined using the MC simulation. In figure 2 kinematic distributions of the observables Q^2 , $p_{T,1}^*$, x_P and z_P as observed in the detector are shown in comparison to the expectations from the reweighted MC simulation. The overall good description of the data is achieved after applying a dedicated weighting of the MC simulation in the variables z_P , x_P and $x_{dijet} = \sum_{1,2} (E^{*jet} - p_z^{*jet})_i / \sum_{HFS} (E^* - p_z^*)_i$. Weights are obtained from the reconstructed kinematic distributions and are applied at the hadron level. This procedure is iterated until a good description of the shapes of the observables is achieved.

The data are corrected for detector inefficiencies, acceptance and finite resolution using the regularised unfolding procedure as implemented in TUnfold [47]. A detector response matrix A , with elements a_{ij} expressing the probability for an observable originating in the generated MC sample from an interval i to be measured in an interval j , is determined using the MC simulation. Migrations from outside the measurement phase space are included by additional rows of the detector response matrix. The domains of jets with $3.0 < p_{T,1}^* < 5.5$ GeV and of events with $0.03 < x_P < 0.04$ are found to be the dominating sources of these migrations. The MC simulation is reweighted in order to describe the data also in these regions beyond the nominal phase space.

Two sources of background are considered in this analysis and are subtracted from the data using Monte Carlo simulations prior to unfolding: diffractive dijet events with $M_Y > 1.6$ GeV and $|t| < 1$ GeV² and background from non-diffractive DIS.

For a background subtracted measurement y_j , the corresponding number of events in the truth bin i , x_i , is found by solving a minimisation problem for a χ^2 function

$$\chi^2 = (y - Ax)^T V_{yy}^{-1} (y - Ax) + \tau^2 x^2, \quad (7)$$

where x and y are vectors defined by y_j and x_i , respectively, V_{yy} is the covariance matrix accounting for the statistical uncertainties of y_j and τ is a regularisation parameter introduced in order to damp statistical fluctuations of the solution. The regularisation parameter τ is determined using the L-Curve scan [47].

The cross section in each measurement interval i is given by

$$\sigma_i(ep \rightarrow ep'X) = \frac{x_i}{\mathcal{L}} (1 + \delta_{i,rad}), \quad (8)$$

where \mathcal{L} is the integrated luminosity of the data sample and $(1 + \delta_{i,rad})$ is the correction for QED radiation effects in the interval i . These corrections are calculated as a ratio of RAPGAP predictions with and without QED radiation simulated. The differential cross section is determined by dividing σ_i by the area of the corresponding interval.

4.5 Systematic uncertainties

The systematic uncertainties induced by experimental effects and by model adequateness are propagated to each measurement interval in the unfolding procedure (eq. 7). A dedicated detector response matrix is constructed for each variation related to particular sources of uncertainties:

- The energy of the scattered electron is varied by $\pm 1\%$ with a resulting uncertainty on the integrated dijet cross section of 1%.
- The polar angle of the scattered electron is varied by ± 1 mrad with a resulting uncertainty on the integrated dijet cross section of 1%.
- The energy of each particle contained in HFS is varied by $\pm 1\%$ [43] which translates into an uncertainty on the integrated dijet cross section of 4%.
- Uncertainties related to the model dependent corrections of the data are accounted for by varying the shape of the kinematic distributions in Q^2 , x_P , β , $p_{T,1}^*$, z_P , x_{dijet} and $\Delta\eta^*$ in the MC such that the data are still described within the statistical uncertainties. For this purpose, the multiplicative weights $(\log Q^2)^{\pm 0.2}$, $x_P^{\pm 0.05}$, $\beta^{\pm 0.01}(1 - \beta^{\pm 0.01})$, $p_{T,1}^{*\pm 0.04}$, $z_P^{\pm 0.15}$, $x_{dijet}^{\pm 0.15}$ and $(1.5 + \Delta\eta^*)^{\pm 0.5}$ are applied, respectively. The largest resulting uncertainty of 3% arises from the variation of the shape in $p_{T,1}^*$. The shape of the distribution in t is varied within the experimental uncertainty on the t -slope [48] by applying a weight of $e^{\pm t}$ in MC, which translates into an uncertainty on the integrated dijet cross section of 1%. The integrated cross section uncertainty due to the model dependence of the measurement is of the order of 5%.

The following uncertainties on the global normalisation are considered:

- The luminosity of the data is measured with a precision $\pm 2.7\%$ [39].
- The trigger efficiency related to the tracking and SpaCal condition induces an uncertainty of 2% and 1%, respectively.
- The uncertainty accounting for the LRG selection efficiency is 7% [49].
- The normalisation of the non-diffractive DIS background modelled by RAPGAP is varied by $\pm 50\%$ and the normalisation of the diffractive background is varied by $\pm 100\%$, yielding a resulting uncertainty on the integrated dijet cross section below 1% in both cases.

The total systematic uncertainty is obtained by adding the individual contributions in quadrature.

5 Results

The integrated cross section in the measurement phase space specified in table 1 is found to be

$$\sigma_{meas}^{dijet}(ep \rightarrow eXY) = 73 \pm 2 \text{ (stat.)} \pm 7 \text{ (syst.) pb} . \quad (9)$$

The NLO QCD prediction of the total diffractive dijet cross section is

$$\sigma_{theo}^{dijet}(ep \rightarrow eXY) = 77^{+25}_{-20} \text{ (scale)}^{+4}_{-14} \text{ (DPDF)} \pm 3 \text{ (had)} \text{ pb} , \quad (10)$$

in very good agreement with the measurement. The uncertainty on the NLO prediction is found to be significantly larger than the experimental uncertainty.

Single differential cross sections are given in tables 2 and 3 and are shown in figures 3-6. The statistical correlations between measurements in different bins are given in tables 6 and 7. The differential cross sections as a function of the DIS variables Q^2 and y are shown in figure 3, as a function of the momentum fractions x_P and z_P are shown in figure 4 and as a function of the jet variables $p_{T,1}^*$, $p_{T,2}^*$, $\langle p_T^* \rangle$ and $\Delta\eta^*$ are shown in Figure 5 and 6. For the majority of the measurements, the data precision is limited by systematic effects. The statistical correlations are small for the inclusive kinematic variables Q^2 and y and moderate ($|\rho| < 0.6$) for the other variables. The figures also include the NLO QCD predictions which describe within their large uncertainties the data well.

The dynamics of dijet production is further studied in terms of double differential cross sections in bins of z_P and of the QCD scale defining observables Q^2 and $p_{T,1}^*$. The double differential cross sections are listed in tables 4-5 and are shown in figures 7-10. The corresponding statistical correlations between measurements in different bins are given in tables 8-9. Figure 7 shows the double differential cross section measured in bins of z_P and Q^2 . The ratio of the data to the theory prediction is shown in figure 8. The data are well described by the NLO prediction in most of the phase space. The double differential cross section measured in bins of $p_{T,1}^*$ and Q^2 is shown in figure 9 and the corresponding ratios of the measurements to the NLO predictions are shown in figure 10.

The present measurement is based on a six times increased luminosity as compared to the previous H1 measurement of dijet production with LRG [13] and is using a more sophisticated data correction method. A direct comparison of the present data to other measurements of dijet production in diffractive DIS is not possible because of different phase space definitions. Measurements based on the direct detection of a forward proton [15] are limited in statistical precision due to the restricted geometrical acceptance of the proton taggers.

The experimental uncertainties on both single- and double-differential cross sections are in general smaller than the theory uncertainties. The data thus have the power to constrain QCD in diffractive DIS. Here, the double-differential dijet cross sections as a function of Q^2 and $p_{T,1}^*$ are used to determine the value of the strong coupling constant $\alpha_s(M_Z)$ at the scale of the mass of the Z-boson, M_Z . The value of $\alpha_s(M_Z)$ is determined by an iterative χ^2 -minimisation procedure using NLO calculations, corrected for hadronisation effects following the method [50]. In the fit, the uncertainties on the HFS energy scale are treated as 50% correlated and 50% uncorrelated. All other experimental uncertainties are treated as correlated. Scale uncertainties, hadronisation

uncertainties and DPDF uncertainties of the NLO calculation are propagated to the fit result as described in [50].

The fit yields a value of $\chi^2/n_{\text{dof}} = 16.7/14$, with n_{dof} being the number of degrees of freedom, thus indicating good agreement of theory to data. The nuisance parameters of the correlated systematic uncertainties are equally distributed around zero with absolute values below one. The value of $\alpha_s(M_Z)$ determined in the fit to the dijet cross sections is

$$\begin{aligned}\alpha_s(M_Z) &= 0.119 \pm 0.004 (\text{exp}) \pm 0.002 (\text{had}) \pm 0.005 (\text{DPDF}) \pm 0.010 (\mu_r) \pm 0.004 (\mu_f) \quad (11) \\ &= 0.119 \pm 0.004 (\text{exp}) \pm 0.012 (\text{DPDF, theo})\end{aligned}$$

The largest uncertainties arise from the estimate of the contributions from orders beyond NLO and from the poor knowledge of the DPDF. The largest contribution to the experimental uncertainty of 0.003 arises from the global normalisation uncertainty.

The result for $\alpha_s(M_Z)$ is consistent within the uncertainties with the world average [51, 52] and with values from other jet data in DIS and photoproduction [50, 53, 54] as well as values of $\alpha_s(M_Z)$ determined from jet data at the Tevatron [55, 56] and at the LHC [57, 58]. Although the uncertainty of this $\alpha_s(M_Z)$ extraction is not competitive with measurements in other processes the agreement with the other measurements supports the underlying concept of treating dijet production in diffractive DIS with perturbative QCD calculations.

6 Conclusions

Integrated, single- and double-differential cross sections of diffractive DIS dijet production are measured with the H1 experiment in ep collisions at HERA and compared with NLO QCD predictions.

The integrated diffractive dijet cross section is found to be well described by the NLO QCD prediction using the H12006 Fit-B DPDF set. Both shapes and normalisation of the single-differential cross sections are reproduced by the theory within the experimental and theory uncertainties, confirming at improved precision the conclusions from previous H1 measurements. Good agreement of the theory with the measurement is also found for the shapes and normalisation of the double differential cross sections. The cross section measurements presented here show experimental uncertainties significantly smaller than the uncertainties of the theory predictions. From a fit of the NLO prediction to the double differential cross sections in Q^2 and $p_{T,1}^*$, the strong coupling constant has been determined to be $\alpha_s(M_Z) = 0.119 (4)_{\text{exp}} (12)_{\text{theo}}$.

Acknowledgements

We are grateful to the HERA machine group whose outstanding efforts have made this experiment possible. We thank the engineers and technicians for their work in constructing and maintaining the H1 detector, our funding agencies for financial support, the DESY technical staff for continual assistance and the DESY directorate for the hospitality which they extend to the non-DESY members of the collaboration. We would like to give credit to all partners contributing to the EGI computing infrastructure for their support for the H1 Collaboration.

Table 2: Diffractive DIS dijet cross section measured differentially as a function of Q^2 , y , $\log x_P$ and z_P . The statistical δ_{stat} and systematic δ_{sys} uncertainties are given together with the total uncertainty δ_{tot} . The next 12 columns represent $+1\sigma$ shifts for the systematic error contributions from: electron polar angle measurement δ_θ , electron energy scale δ_E , HFS energy scale δ_{HFS} , model uncertainties δ_{Q^2} , δ_{x_P} , δ_β , $\delta_{p_{*T,1}}$, δ_{z_P} , $\delta_{x_{dijet}}$, $\delta_{\Delta\eta^*}$ and δ_t and the background normalisation uncertainty δ_{bgr} . The global normalisation uncertainty of 7.8% is not listed explicitly but is included in the total systematic uncertainty δ_{sys} . The last two columns show the correction factors for hadronisation and QED radiation, respectively.

	34 ÷ 100	15															100

Table 9: Correlation coefficients between data points for the double-differential measurement in $p_{T,1}^*$ and Q^2 . The values are given in per cent.

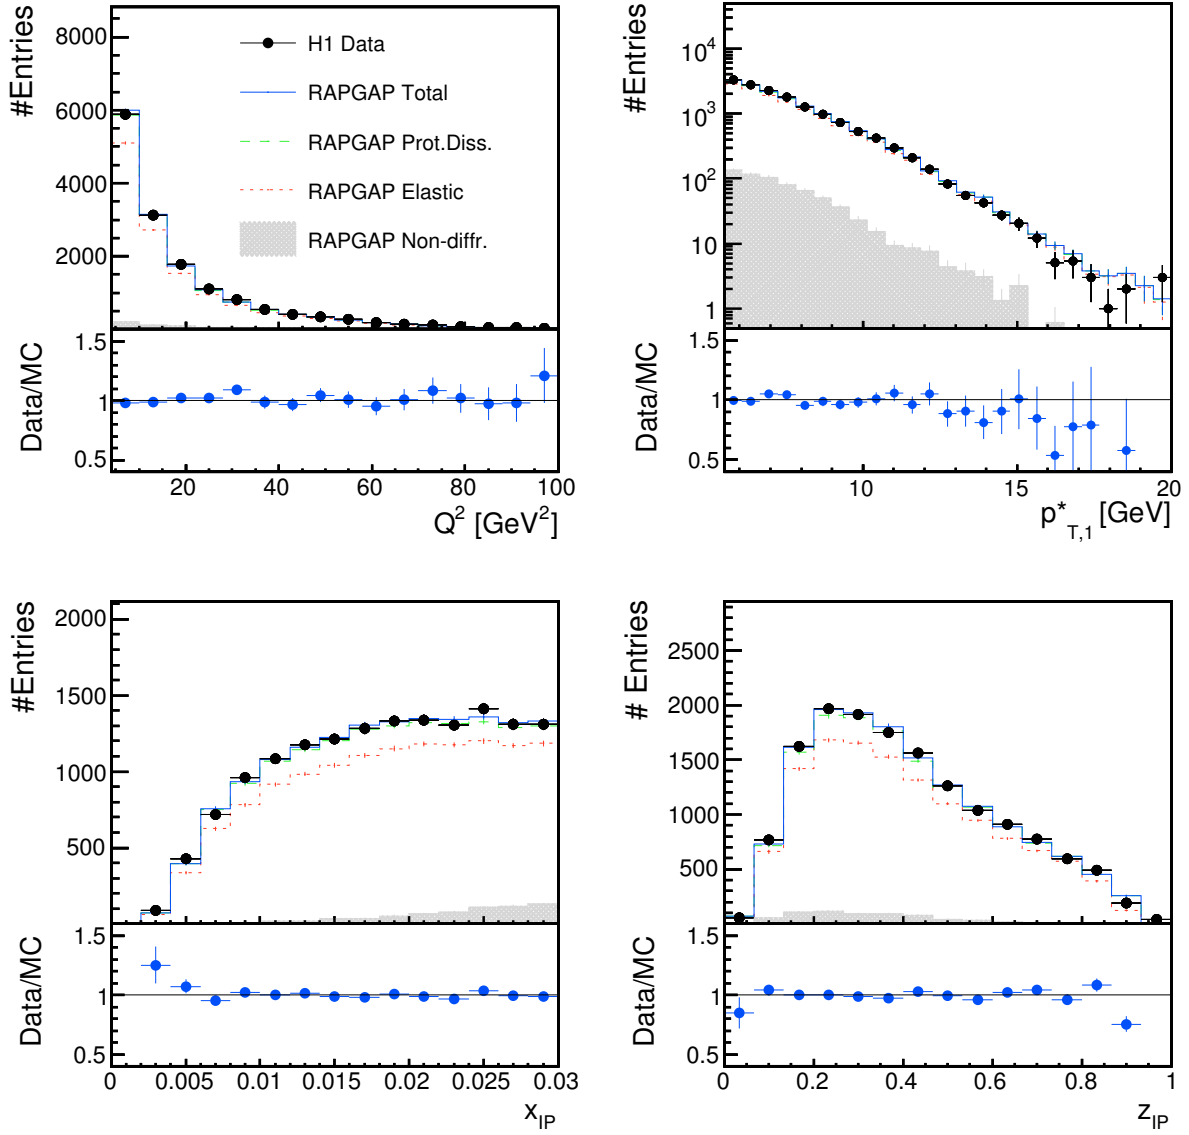

Figure 2: Distributions of the kinematic quantities Q^2 , $p_{T,1}^*$, x_P and z_P . The data are shown as black points compared to the sum of MC simulation estimates. The filled area shows the contribution of non-diffractive DIS, the dotted line shows the diffractive contribution with the elastically scattered proton added to the non-diffractive DIS and the dashed line displays the proton dissociation contribution added to the diffractive contribution with the elastically scattered proton and the non-diffractive DIS contribution. The sum of all contributions including the resolved photon processes is given by the full line. The MC is reweighted to the data. The ratio of data to the MC prediction is shown in the lower part of the individual figures.

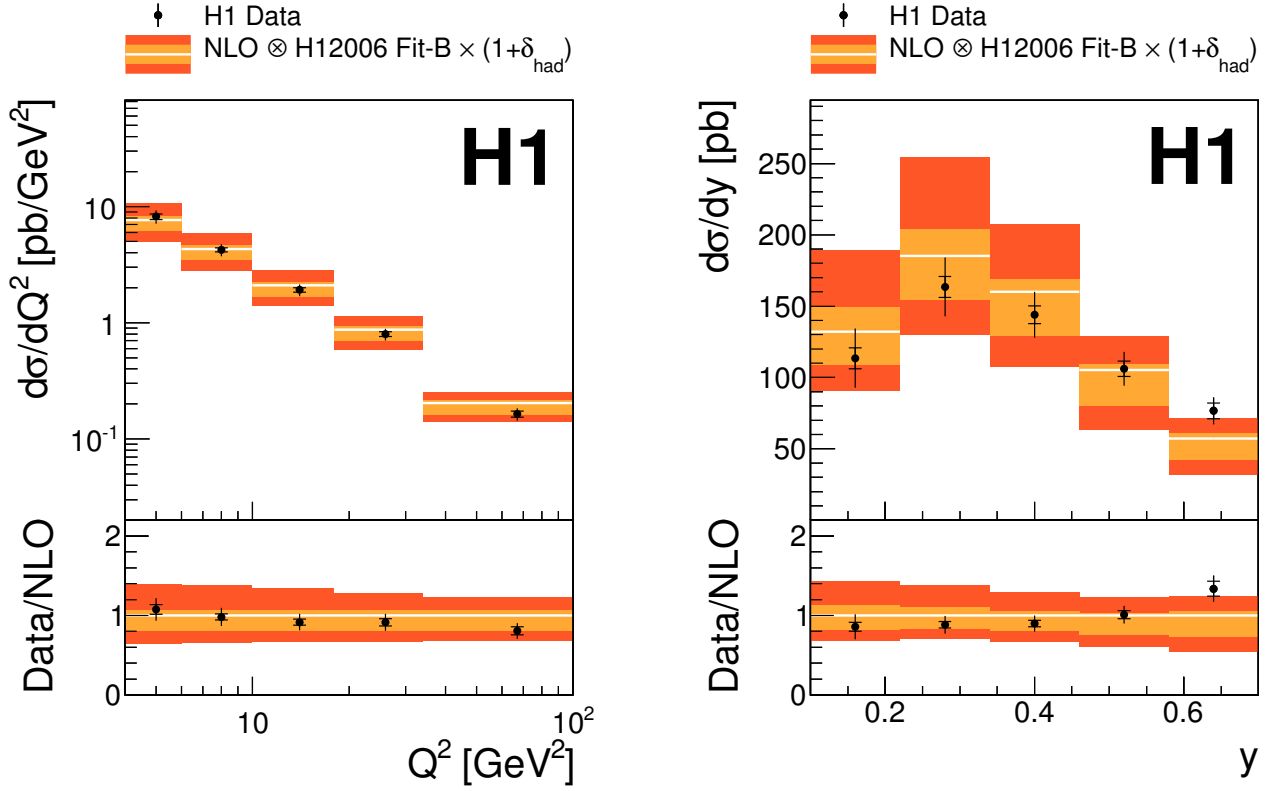

Figure 3: Diffractive dijet differential cross section as a function of Q^2 and y . The inner error bars on the data points represent the statistical uncertainties, while the outer error bars include the systematic uncertainties added in quadrature. The NLO QCD prediction based on the H12006 Fit-B DPDF set is displayed as a white line. The light shaded band indicates the uncertainty arising from hadronisation and the DPDF fit added in quadrature. The outer dark band shows the full theory uncertainty including the QCD scale uncertainty added in quadrature. The ratio of the single-differential cross section to the NLO prediction is shown in the lower part of the individual figures.

Figure 4: Diffractive dijet differential cross section as a function of $\log x_P$ and z_P . The inner error bars on the data points represent the statistical uncertainties, while the outer error bars include the systematic uncertainties added in quadrature. Further details are given in figure 3.

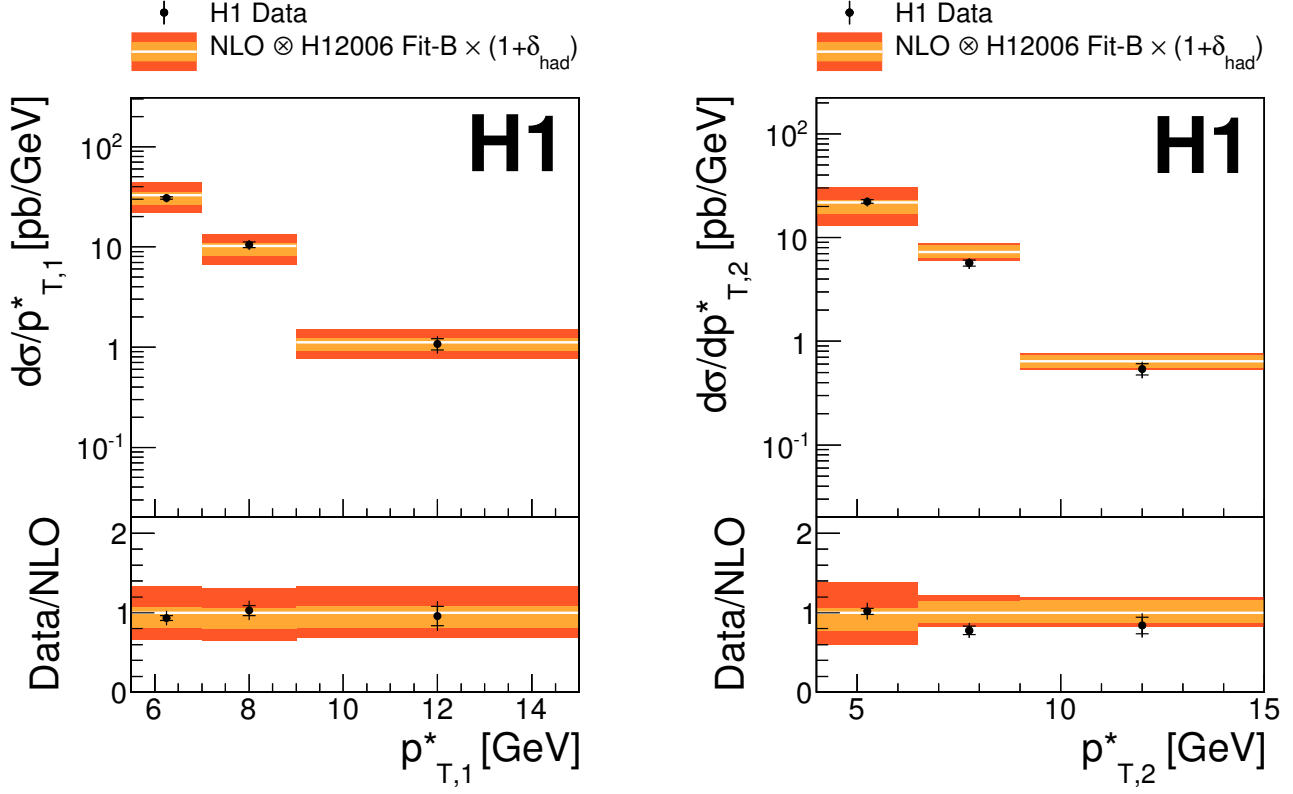

Figure 5: Diffractive dijet differential cross section as a function of $p_{T,1}^*$ and $p_{T,2}^*$. The inner error bars on the data points represent the statistical uncertainties, while the outer error bars include the systematic uncertainties added in quadrature. Further details are given in figure 3.

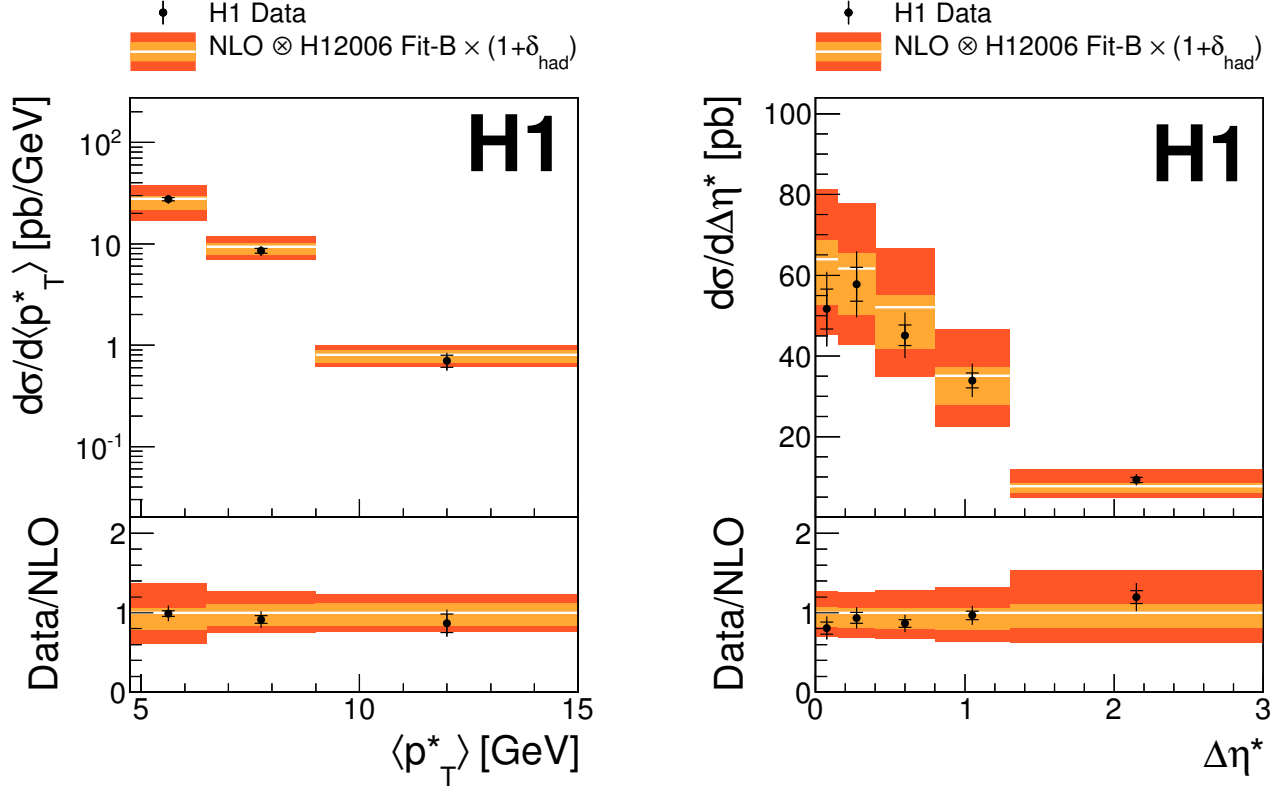

Figure 6: Diffractive dijet differential cross section as a function of $\langle p_T^* \rangle$ and $\Delta\eta^*$. The inner error bars on the data points represent the statistical uncertainties, while the outer error bars include the systematic uncertainties added in quadrature. Further details are given in figure 3.

Figure 7: Double-differential cross section as a function of z_P and Q^2 . The inner error bars on the data points represent the statistical uncertainties, while the outer error bars include the systematic uncertainties added in quadrature. Further details are given in figure 3.

Figure 8: Ratio of the double-differential cross section to the NLO prediction as a function of z_P and Q^2 . The inner error bars on the data points represent the statistical uncertainties, while the outer error bars include the systematic uncertainties added in quadrature. Further details are given in figure 3.

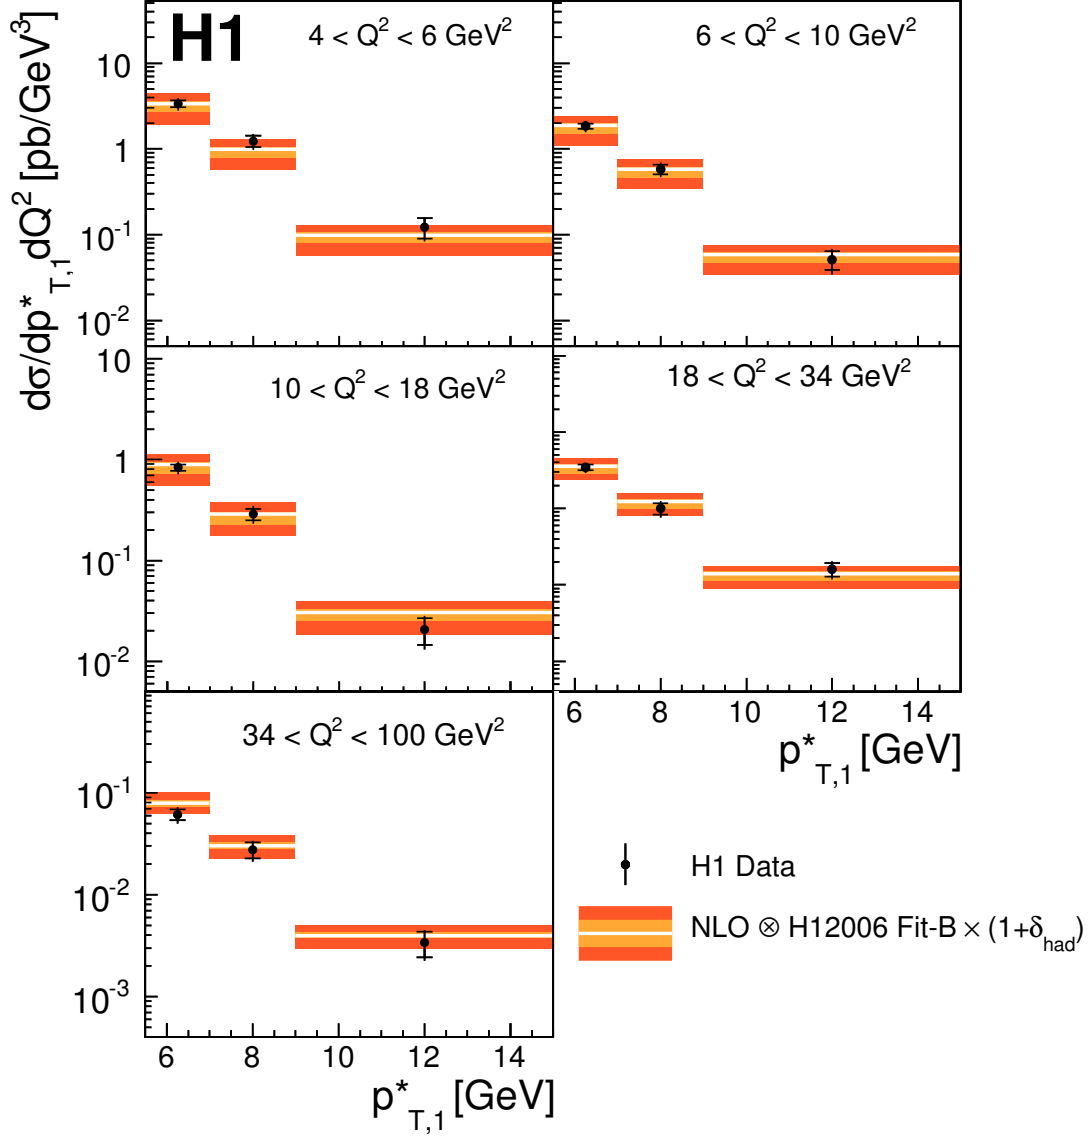

Figure 9: Double-differential cross section as a function of $p_{T,1}^*$ and Q^2 . The inner error bars on the data points represent the statistical uncertainties, while the outer error bars include the systematic uncertainties added in quadrature. Further details are given in figure 3.

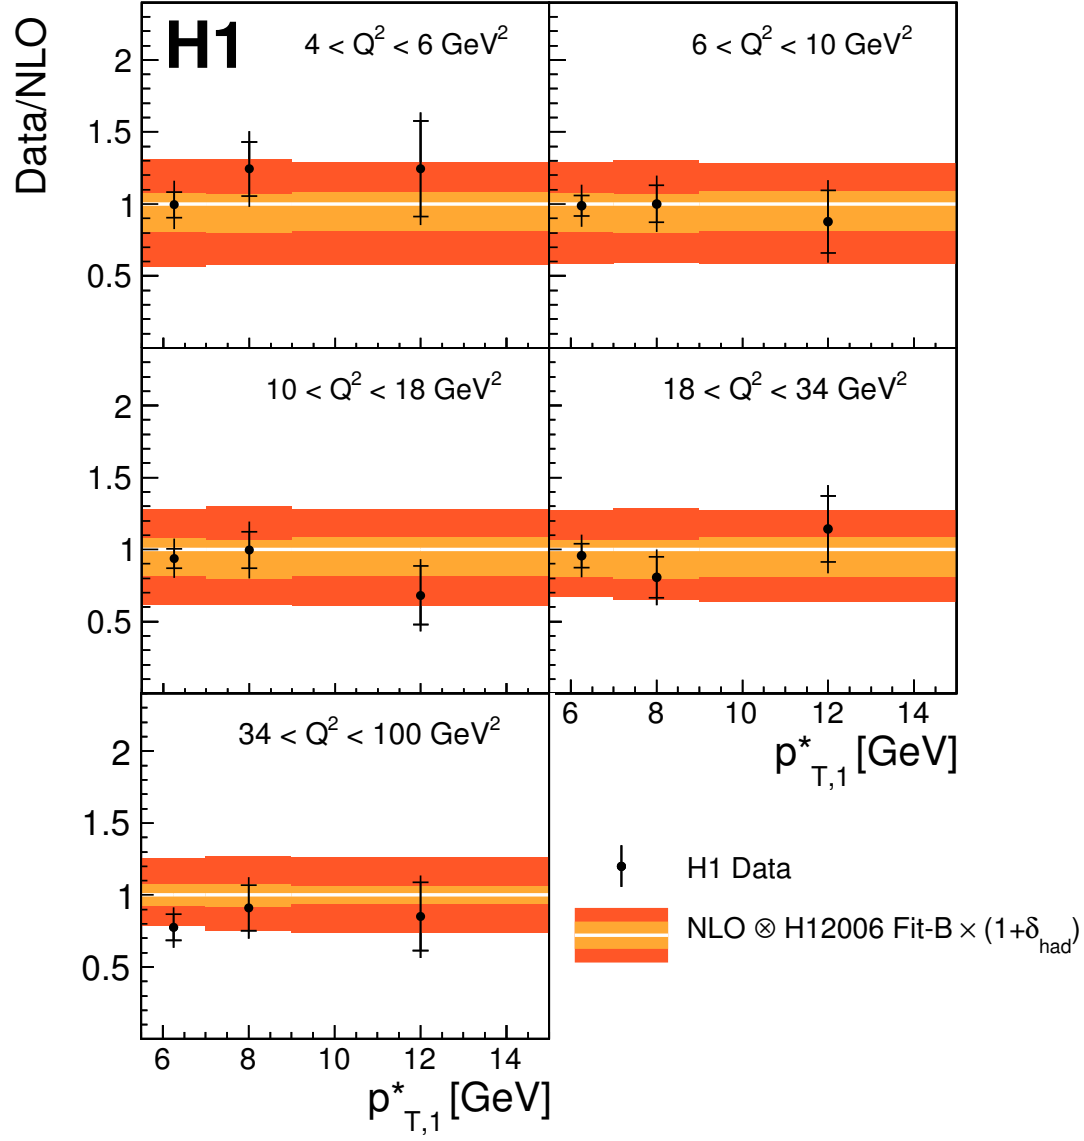

Figure 10: Ratio of the double-differential cross section to the NLO prediction as a function of $p_{T,1}^*$ and Q^2 . The inner error bars on the data points represent the statistical uncertainties, while the outer error bars include the systematic uncertainties added in quadrature. Further details are given in figure 3.
