Improved steel cleanliness analysis with inclusion detection and quantification using synchrotron X-ray microtomography

THE INDUSTRIAL CHALLENGE

Foreign particles (inclusions) in steel, originating from early stages in the steel production process may reduce mechanical properties. As a world leading steel producer SSAB constantly strives to improve the cleanliness of the steel and one key is improved methods for the detection and quantification of inclusions.

WHY USING A LARGE SCALE FACILITY

Present standard techniques to investigate steel cleanliness are 2-dimensional (2D), e.g. light optical microscopy (LOM) and scanning electron microscopy (SEM). These methods are limited since interpretation by stereographic methods and assumption of a regular inclusion size distribution must be done in order to obtain size, shape and volume fraction of the inclusions. Difficulties arise when inclusions are few or when there is a varying orientation or shape of inclusion particles and irregularities in the inter-particle connectivity. The 3D nature of non-destructive tomographic imaging techniques can overcome this. The low X-ray intensity of laboratory-based X-ray tomography (CT) demands for a longer scan time, thus making impeding the technique to be used on a commercial basis. With the high beam brilliance at a modern synchrotron source, X-ray microtomography SR CT is less time consuming. Following the recent developments and increased availability of SR CT combined with optimized work-flows for image analysis, this technique could potentially be offered as a standard and routinely used technique for industrial inclusion assessments.

HOW THE WORK WAS DONE

The inclusion detection and quantification SR CT experiments were performed at the P07 High Energy Materials Science (HEMS) beamline of Helmholtz-Zentrum Geesthacht

at the PETRA III storage ring at the DESY synchrotron in Hamburg, Germany. 12 samples of low carbon steel were prepared as rods with 10 mm height and 1-2 mm in diameter. To validate the results of the SR CT measurements, standard testing was done using microscopy methods, i.e. LOM and SEM.

THE RESULTS AND EXPECTED IMPACT

With the SR CT method, it was possible to detect inclusions down to the size of 2.4 μ m, which is similar to standard 2D techniques, however with a much shorter scan time, about 15 min compared to several hours for standard 2D techniques. The image below shows a 3D rendering of a sample volume, where the inclusions are clearly visible.

3D rendered volume of a sample rod from SR CT.

For image analysis of individual inclusions, an automatic image analysis script in Python was developed. The quantitative results of SR CT, LOM and SEM showed strong mutual correlation. Also, the SR CT revealed the actual size distribution of the inclusions in the samples. Proven as a fast and precise method for 3D inclusion assessment, a very interesting next step would be to test steels for correlation between SR CT data and relevant mechanical properties.
