PACS 41.20.Gz – Magnetostatics; magnetic shielding, magnetic induction, boundary-value problems

**Abstract** – We propose an experiment to search for extra “hidden-sector”  $U(1)$  gauge bosons with small gauge kinetic mixing  $\chi$  with the ordinary photon, predicted by many extensions of the Standard Model. The setup consists of a highly sensitive magnetometer inside a superconducting shielding which are in turn placed inside a strong (but sub-critical) magnetic field. Photon – hidden-sector photon – photon oscillations would allow the magnetic field to “leak” into the shielded volume and register on the magnetometer. In our setup the magnetometer directly measures the field strength ( $\propto \chi^2$ ), improving the sensitivity over “light-shining-through-walls” experiments which measure the regeneration probability ( $\propto \chi^4$ ). In the mass range  $2\mu\text{eV} \lesssim m_{\gamma'} \lesssim 200\text{meV}$  the projected sensitivity is in the  $\chi \sim 5 \times 10^{-9}$  to  $\chi \sim 10^{-6}$  range. This surpasses current astrophysical and laboratory limits by several orders of magnitude — ample room to discover new physics.

In the near future the LHC will commence searching for new particles with masses of the order of a TeV. This will test many proposed extensions of the Standard Model as, *e.g.*, supersymmetry, large extra dimensions, technicolor to name only a few. However, many extensions of the Standard Model contain additional hidden sectors that interact only very weakly with ordinary matter. Due to their feeble interactions even light particles in such hidden sectors may be missed in such a collider experiment. Yet, it may be exactly these hidden sectors that carry crucial information on how the Standard Model is embedded in a more fundamental theory. This creates the need for complementary experiments.

One interesting class of hidden-sector particles is extra  $U(1)$  gauge bosons. Indeed, many string theory models contain hidden-sector  $U(1)$ 's under which Standard Model particles are uncharged. At low energies, the only renormalizable interaction with the visible sector can occur via mixing [1–3] of the photon  $\gamma$  with the hidden-sector photon  $\gamma'$ . Current experimental bounds are shown in fig. 1 (see footnote <sup>1</sup>). Interestingly there is a dip in the sensitivity in the mass region around 1 meV. Hidden-sector photons in

Fig. 1: (Colour on-line) Current bounds on hidden-sector photons from Coulomb law tests [6,7] (green), CAST solar  $\gamma'$  searches (purple) [8–11], light-shining-through-walls (LSW) experiments (grey) [12–14] (taken from [15,16]) and distortions of the CMB [17–20]. The blue (red) line shows the sensitivity of the proposed experiment in a conservative (optimistic) scenario. See the text for details.

<sup>1</sup>A way to improve the solar bounds has been proposed recently [4]. The region  $m_{\gamma'} \lesssim 1\text{meV}$  could also be tested by an experiment using microwave cavities [5].

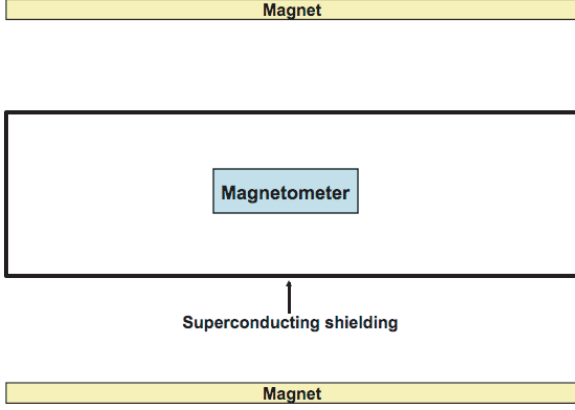

Fig. 2: (Colour on-line) Illustration of the principle of the experiment proposed in this paper. Ordinary magnetic fields are shielded by the superconductor. However, if a hidden  $U(1)$  field mixes with the ordinary electromagnetic field some of the magnetic field can convert into a hidden magnetic field, pass through the superconductor and reconvert into an ordinary magnetic field inside the shielding. This field can then be measured by a highly sensitive magnetometer.

this mass region could, *e.g.*, explain [20] the slight excess in the number of relativistic species observed in combinations of CMB with Lyman- $\alpha$  data [21,22] (although this could also be due to systematics [23]). Moreover, one might (wildly) speculate about possible connections to neutrino masses and dark energy which incidentally also have energy scales around meV. The experiment proposed in this letter is designed to search for hidden-sector photons exactly in this region.

The basic idea of the proposed experiment is very similar to a classic “light-shining-through-a-wall experiment” (LSW). However, instead of light it uses a static magnetic field and the wall is replaced by superconducting shielding (cf. fig. 2). Outside the shielding we have a strong magnetic field. Upon entering the superconductor the ordinary electromagnetic field is exponentially damped with a length scale given by the London penetration depth  $\lambda_{\text{Lon}}$ . Yet, due to the photon – hidden-photon mixing a small part of the magnetic field is converted into a hidden magnetic field. After the superconducting shield is crossed the mixing turns a small fraction of the hidden magnetic field back into an ordinary magnetic field that can be detected by a magnetometer. Since the magnetometer measures directly the field (and not some probability or power output) the signal is proportional to the transition amplitude and therefore to the mixing squared,  $\chi^2$ , instead of being proportional to  $\chi^4$ . In this sense it is more similar to the tests of Coulomb law [6,7] than to an LSW experiment.

Let us start from the Lagrangian describing the photon – hidden-sector photon system at low energies,

$$\mathcal{L} = -\frac{1}{4}F^{\mu\nu}F_{\mu\nu} - \frac{1}{4}B^{\mu\nu}B_{\mu\nu} - \frac{1}{2}\chi F^{\mu\nu}B_{\mu\nu} + \frac{1}{2}m_{\gamma'}^2 B_\mu B^\mu + j_\mu A^\mu + \frac{1}{2}M_{\text{Lon}}^2 A_\mu A^\mu, \quad (1)$$

where  $F_{\mu\nu}$  is the field strength tensor for the ordinary electromagnetic  $U(1)_{\text{QED}}$  gauge field  $A^\mu$ ,  $j^\mu$  is its associated current (generated by electrons, etc.) and  $B^{\mu\nu}$  is the field strength for the hidden-sector  $U(1)_{\text{hid}}$  field  $B^\mu$ . The first two terms are the standard kinetic terms for the photon and hidden-photon fields, respectively. Because the field strength itself is gauge invariant for  $U(1)$  gauge fields, the third term is also allowed by gauge and Lorentz symmetry. This term corresponds to a non-diagonal kinetic term, the so-called kinetic mixing [2]. This term is a renormalizable dimension four term and does not suffer from mass suppressions. It is therefore a sensitive probe for physics at very high energies. Kinetic mixing arises in field-theoretic [2] as well as in string-theoretic setups [24–30]. Typical predicted values for  $\chi$  in realistic string compactifications range between  $10^{-16}$  and  $10^{-2}$ . The second to last term is a mass term for the hidden-photon. This could either arise from a Stückelberg [31] or Higgs mechanism, although in this last case additional observational constraints apply [32]. Finally, the last term corresponds to the London mass  $M_{\text{Lon}} = 1/\lambda_{\text{Lon}}$  the photon acquires inside a superconductor. In vacuum  $M_{\text{Lon}} = 0$ .

From this Lagrangian we obtain the equations of motion

$$\begin{aligned} \square(A^\mu + \chi B^\mu) + M_{\text{Lon}}^2 A^\mu + j^\mu &= 0, \\ \square(\chi A^\mu + B^\mu) + m_{\gamma'}^2 B^\mu &= 0. \end{aligned} \quad (2)$$

Here, we have chosen Lorentz gauge for the massless field (if  $M_{\text{Lon}}^2 = 0$ ) and used that the Lorentz condition is automatically enforced for massive fields.

Due to the kinetic mixing, a source  $j^\mu$  originating from purely standard model fields, *i.e.* typically electrons, will automatically generate also a small  $B^\mu$  field: very close to a localized source the field equations (2) are dominated by the derivative terms and the mass terms can be neglected. Accordingly the second equation in (2) can only be fulfilled if the generated field is proportional to  $(A, B) \sim (1, -\chi)$ . Having said this, we will drop the source from now on.

Taking appropriate derivatives in (2) we get the equations for the field strengths

$$\begin{aligned} \square(F^{\mu\nu} + \chi B^{\mu\nu}) + M_{\text{Lon}}^2 F^{\mu\nu} &= 0, \\ \square(\chi F^{\mu\nu} + B^{\mu\nu}) + m_{\gamma'}^2 B^{\mu\nu} &= 0. \end{aligned} \quad (3)$$

The essential features can be studied by using an one-dimensional setup: the superconductor would be then infinite filling the (2, 3)-plane and having a thickness  $d$ . The distances from the source of the magnetic field to the superconducting plane and from there to the detector will be called  $L_1$  and  $L_2$ , respectively. Note that the different space-time components of eq. (3) decouple and fulfill the same equations so essentially we can drop the space-time indices. As an example let us choose a static magnetic field in the 3-direction, *i.e.* only the 12 components are non-vanishing,  $F^{12} = \mathbf{B}$  and  $B^{12} = \mathbf{B}_{\text{hid}}$ . We find,

$$\begin{aligned} \partial_1^2(\mathbf{B} + \chi \mathbf{B}_{\text{hid}}) - M_{\text{Lon}}^2 \mathbf{B} &= 0, \\ \partial_1^2(\chi \mathbf{B} + \mathbf{B}_{\text{hid}}) - m_{\gamma'}^2 \mathbf{B}_{\text{hid}} &= 0. \end{aligned} \quad (4)$$

Outside the superconductor  $M_{\text{Lon}}^2 = 0$  and to lowest non-trivial order in  $\chi$  the non-growing solutions are

$$V_1(x) = \begin{pmatrix} 1 \\ 0 \end{pmatrix}; \quad V_2(x) = \begin{pmatrix} -\chi \\ 1 \end{pmatrix} \exp(-m_{\gamma'} x), \quad (5)$$

in the  $(\mathbf{B}, \mathbf{B}_{\text{hid}})$  basis. As discussed above, close to the source the magnetic field will be  $\sim (1, -\chi)$ . However, we can now see that the small  $\mathbf{B}_{\text{hid}}$  component is exponentially damped. Therefore, after a distance  $\gg 1/m_{\gamma'}$ , the field is  $\propto V_1$  and will stay that way until it reaches the superconductor.

Inside the superconductor the solutions are

$$\begin{aligned} V_1^{\text{sc}}(x) &= \begin{pmatrix} 1 - \frac{m_{\gamma'}^2}{M_{\text{Lon}}^2} \\ -\chi \end{pmatrix} \exp(-M_{\text{Lon}} x), \\ V_2^{\text{sc}}(x) &= \begin{pmatrix} \frac{m_{\gamma'}^2}{M_{\text{Lon}}^2 - m_{\gamma'}^2} \chi \\ 1 \end{pmatrix} \exp(-m_{\gamma'} x). \end{aligned} \quad (6)$$

Note that  $V_2^{\text{sc}}$  is damped with  $m_{\gamma'}$  and not  $M_{\text{Lon}}$ . For  $m_{\gamma'} \ll M_{\text{Lon}}$  the mainly hidden photon like  $V_2^{\text{sc}}$  can therefore “leak” through the superconducting shielding.

Therefore, for  $L_1 \gg 1/m_{\gamma'}$  (distant source) and using  $m_{\gamma'}^2 \ll M_{\text{Lon}}^2$  for simplicity, we have

$$\begin{pmatrix} \mathbf{B}(L_1) \\ \mathbf{B}_{\text{hid}}(L_1) \end{pmatrix} = \mathbf{B}_0 \begin{pmatrix} 1 \\ 0 \end{pmatrix} = \mathbf{B}_0 (V_1^{\text{sc}}(0) + \chi V_2^{\text{sc}}(0)). \quad (7)$$

For  $m_{\gamma'}^2 \ll M_{\text{Lon}}^2$  and  $1/m_{\gamma'} \gg d \gtrsim \text{few} \times 10 \lambda_{\text{Lon}}$  only the component  $V_2^{\text{sc}}(x)$  effectively penetrates the shielding and

$$\begin{pmatrix} \mathbf{B}(L_1 + d) \\ \mathbf{B}_{\text{hid}}(L_1 + d) \end{pmatrix} \simeq \mathbf{B}_0 \chi V_2^{\text{sc}}(d) \simeq \mathbf{B}_0 \chi \begin{pmatrix} 0 \\ 1 \end{pmatrix} = \chi^2 V_1(0) + \chi V_2(0). \quad (8)$$

At a distance  $L_2 \gg 1/m_{\gamma'}$  after the shielding only the  $V_1$  component survives and the measurable ordinary magnetic field approaches  $\mathbf{B}_{\text{meas}} \equiv \mathbf{B}(L_1 + d + L_2) \simeq \mathbf{B}_0 \chi^2$ .

Keeping somewhat more carefully track of the exponentials we find

$$\frac{\mathbf{B}_{\text{meas}}}{\mathbf{B}_0} = e^{-M_{\text{Lon}} d} + \chi^2 e^{-m_{\gamma'} d} [1 - e^{-m_{\gamma'} L_1}] [1 - e^{-m_{\gamma'} L_2}]. \quad (9)$$

The first part is the standard “leaking” expected from the finite thickness of the superconducting shielding, and constitutes the Standard Model background. The second part  $\sim \chi^2$  is the signal caused by the hidden photons. The first exponential arises from the damping of the hidden-photon field inside the superconducting shield whereas the terms in brackets account for the fact that the conversion of photons into hidden photons and vice versa takes place over length scales  $\sim 1/m_{\gamma'}$ . The evolution of  $\mathbf{B}$  and  $\mathbf{B}_{\text{hid}}$  from the source to the detector is sketched in fig. 3.

Let us now turn to the sensitivity of such an experiment. Magnetic-field strengths  $\mathbf{B}_0$  of the order 1–5 T can

Fig. 3: (Colour on-line) Dependence of the magnetic field  $\mathbf{B}$  (blue) and hidden magnetic field  $\mathbf{B}_{\text{hid}}$  (red) as a function of the distance from the source ( $x_1$ ) in our 1-dimensional setup. Both quantities are normalized to the value  $\mathbf{B}_0$ . The dotted line represents the evolution of  $\mathbf{B}$  in the absence of the hidden field ( $\chi \rightarrow 0$ ). Near the external (left) surface of the superconducting shield  $\mathbf{B}_{\text{hid}}$  changes sign from negative to positive, hence the abrupt fall to zero. For better visibility we have chosen not too extreme values:  $\chi = 10^{-4}$ ,  $m_{\gamma'} L_1 = m_{\gamma'} L_2 = 5$ ,  $m_{\gamma'} d = 1$  and  $23 m_{\gamma'} = M_{\text{Lon}}$ . For  $m_{\gamma'} d \ll 1 \ll L_{1,2} m_{\gamma'}$  the evolution approaches  $\chi^2$ , but for the chosen parameters the result is a bit smaller because the hidden field is a bit damped inside the shielding due to  $m_{\gamma'} d = 1$ .

be reached in the laboratory. However, we have to stay below the critical-field strength of the superconductor. In most materials this ranges between 0.01 T and 0.2 T [33] although fields as high as 1 T can be shielded in certain cases (cf., e.g. [34]). Modern magnetometers [35–37] can detect magnetic fields as low as  $\mathbf{B}_{\text{detect}} = 5 \times 10^{-18}$  T and  $\mathbf{B}_{\text{detect}} = 1 \times 10^{-13}$  seems relatively conservative. Accordingly, we can expect a sensitivity in the  $\chi \sim 10^{-6}$  to  $5 \times 10^{-9}$  range. It should be noted that the shielding of a  $\mathcal{O}(0.1 \text{ T})$  magnetic field down to  $\mathcal{O}(10^{-18} \text{ T})$  is certainly an experimental challenge. However, shielding on this level has been achieved [35]. Concerning the use of SQUIDs as magnetometers a comment is in order. SQUIDs can only measure *changes* in the magnetic flux. Two possibilities to solve this problem are to modulate the strength of the external magnetic field or to change its direction, by rotating it for example. The concrete magnet to use will be determined in part by the chosen modulation scheme, the intensity can be easily modulated in an electromagnet or superconducting magnet while a permanent magnet could be preferable if we choose the modulation of the field direction. As long as the time scale for the change in the magnetic field is long compared to  $m_{\gamma'}$  the above considerations remain unchanged. In addition, time-modulated magnetic fields might also be helpful in reducing the background.

Finally, we have to ask which mass scales we can probe in the experiment. From (9) we can read off that optimal sensitivity requires  $L_1, L_2 \gg 1/m_{\gamma'} \gg d \gg 1/M_{\text{Lon}}$ . Typical London penetration depths  $\lambda_{\text{Lon}} = 1/M_{\text{Lon}}$  are of the order of 20–100 nm (cf., e.g., [38]). To avoid fields leaking directly through the shielding (without having to convert into hidden fields) at the  $10^{-20}$  level we need  $d \gtrsim 50 \lambda_{\text{Lon}} \sim 1\text{--}5 \mu\text{m}$ . The requirement  $1/m_{\gamma'} \gg d$  then allows, in principle, to search for masses up to 0.2–0.04 eV. With thicker than the minimal required shielding the experiment will be sensitive only to smaller masses. Finally, the maximal size of the magnetic field and the shielded volume will typically be of the order of a few  $\times 10$  cm. This suggests a lower limit  $\sim 2 \mu\text{eV}$ . Overall we have

$$\begin{aligned} \text{Sensitivity: } 5 \times 10^{-9} \lesssim \chi \lesssim 10^{-6}, \\ \text{for } 2 \mu\text{eV} \lesssim m_{\gamma'} \lesssim 0.2\text{--}0.04 \text{ eV}. \end{aligned} \quad (10)$$

Two examples for the expected sensitivity in our 1D idealization are shown in fig. 1. The blue area corresponds to a conservative estimate for the magnetometer sensitivity  $\mathbf{B}_{\text{detect}} \sim 10^{-14}$  T, and a thickness of the shielding  $d \sim 0.1$  mm —much greater than the theoretical minimum required to have sufficient shielding— an external field of  $\mathbf{B}_0 = 0.05$  T is assumed. The red area is an optimistic scenario,  $\mathbf{B}_{\text{detect}} \sim 5 \cdot 10^{-18}$  T,  $d \sim 50 \lambda_{\text{Lon}} \sim 1 \mu\text{m}$  and  $\mathbf{B}_0 = 0.2$  T. (For both scenarios we used  $L_1 = 10$  cm for the distance from the magnetic-field source to the shield and  $L_2 = 5$  cm for the distance from the shield to the magnetometer.)

In conclusion: we have proposed a simple experiment to search for massive hidden photons. The experiment could improve upon existing bounds by several orders of magnitude in a mass range  $2 \mu\text{eV} \lesssim m_{\gamma'} \lesssim 0.2\text{--}0.04$  eV where existing bounds are relatively weak. It therefore bears significant discovery potential for hidden-sector physics at the meV scale. In particular, it could test recent speculations [20] that the excess in the observed number of relativistic degrees of freedom at decoupling of the CMB originates from a resonant production of hidden photons in the early universe.
